EDITED FOR THE CONGRESS

BY

JOHN ASHHURST, Jr., A.M., M.D.,

FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA, PROFESSOR OF CLINICAL SURGERY IN THE UNIVERSITY OF PENNSYLVANIA, SURGEON TO THE EPISCOPAL HOSPITAL AND TO THE CHILDREN'S HOSPITAL, CONSULTING SURGEON TO ST. CHRISTOPHER'S HOSPITAL AND TO THE HOSPITAL OF THE GOOD SHEPHERD, ETC.

PHILADELPHIA:
PRINTED FOR THE CONGRESS.
1877.

PHILADELPHIA
COLLINS, PRINTER,
705 Jayne Street.

PREFACE.

In explanation of the delay which has attended the publication of the present volume, the Editor would invite attention to the diversified character of its contents, which has necessitated the sending of proof-sheets to more than threescore authors, residing in all portions of the country, and has thus required a much greater expenditure of time than would have been needed under other circumstances.

The volume contains all the Addresses delivered before the Congress in its General Sessions, and, with few exceptions, all the Papers read in the meetings of the several Sections, and by them recommended for publication. Abstracts of the Discussions which ensued upon the reading of the several papers, are also appended in many instances, and, it is believed, will be found to add materially to the interest of the whole.

A few papers have been withdrawn by their authors, and three have been omitted by the Committee of Publication: one on account of its inappropriateness to the work of the Section before which it was read, and of its fragmentary nature, the paper to which it was really but an introduction not having been furnished by the author; another on account of the great expense which would have attended the reproduction of the drawings with which it was illustrated, and without which it would have been valueless; and a third because, though it was referred to the Committee by the Section before which it was read, yet the President and Secretary, and several prominent members, of the Section, afterwards united in declaring that it had been so referred by mistake, and that it was not designed for publication. One paper which was recommended for publication has not been received, and appears to have been lost before the records of the Congress were placed in the Committee's hands.

Two papers were considered too voluminous for the Transactions, and are, therefore, represented by condensed abstracts, one furnished by the author, and the other by the Secretary of the Section to which it had been presented. The Committee of Publication has not felt justified in rejecting any paper on the sole ground of want of merit, after it had been deliberately approved by the Section which heard it read, and to which the responsibility of accepting or refusing it properly belonged; but, in justice to itself, the Committee cannot avoid expressing the

opinion that, in some few instances, the censorship exercised by the Sections might properly have been more rigid.

To the actual proceedings of the Congress and of its several Sections, are prefixed Lists of the Officers and Members of the Congress, the Minutes of the General Sessions, the Address of Welcome of the President, Professor Gross, and, in order to complete the history of the Congress, a brief account of its inception and of the Centennial Medical Commission, prepared by Dr. Hutchinson.

Though authorized by a resolution of the Congress to call upon each delegate for a further contribution towards the expense of issuing the volume, the Committee of Publication determined, after mature deliberation, that it would be better not to make an additional assessment, but to endeavor, by the exercise of a careful supervision, to reduce the cost of the volume to the sum actually in hand from registration-fees and from subscriptions; this has been done, and the Committee has the satisfaction of terminating its labors with no deficit in the treasury.

The Editor offers his sincere thanks to the other members of the Committee of Publication for the cordial support which they have uniformly extended to him in the laborious, and occasionally ungrateful, duties of his office. For any errors which may be detected in his work, and he does not presume to hope that many such do not exist, he bespeaks the friendly indulgence of the reader; and, in bringing his task to a close, he ventures to express a hope that this volume, on which he has expended more than a year of arduous labor, may be found to furnish a not unsatisfactory memorial of the meetings of that important body of which it records the acts—the First International Medical Congress of America.

JOHN ASHHURST, Jr.

2000 West DeLancey Place,
Philadelphia, October, 1877.

THE

CENTENNIAL MEDICAL COMMISSION AND THE INTERNATIONAL MEDICAL CONGRESS.

BY

JAMES H. HUTCHINSON, A.M., M.D.,

OF PHILADELPHIA.

The project of holding an International Medical Congress in Philadelphia, during the Centennial Anniversary of the Declaration of Independence by the United States, seems to have been entertained by the profession as early as 1872, and to have grown out of a resolution originally introduced by Dr. J. G. Stetler, at a meeting of the Philadelphia County Medical Society, held in October of that year. This resolution proposed that a general conference of the different medical societies and colleges in the city should be held to determine what part the medical profession should take in the approaching celebration, which was just then beginning to excite general interest in the community. The form which the proposed celebration should assume, had not, however, been fully agreed upon, and the time at which it was to take place was still far off in the future. Moreover, its advocates had not yet succeeded in convincing our people that it was destined to be one of the great events in our history. Under these circumstances it is not surprising that Dr. Stetler's resolution did not bear immediate fruit, and that the subject was allowed to lie dormant for more than a year.

The question was, however, reopened in January, 1874, in the same society, which then appointed a committee, consisting of Drs. L. Turnbull, J. G. Stetler, and M. O'Hara, to take the matter into consideration. This committee, in due time, reported in favor of the project, and proposed the Fourth of July, 1876, as the day upon which the Congress should begin its sessions. It recommended, also, that the other medical societies of the city should be requested to appoint committees to co-operate with that of the County Society in preparing a plan. At this time, but one other society responded to the request; and the committee soon after, finding that it did not fully represent the profession in the city, extended invitations to several prominent physicians to take part in its deliberations. These invitations were in most instances cordially accepted. The committee, thus increased in numbers and influence,

organized on the 29th of March, 1875, as "The Centennial Medical Commission of Philadelphia," with the following officers:—

President.
Samuel D. Gross, M.D., LL.D., D.C.L. Oxon.

Vice-Presidents.
Alfred Stillé, M.D., LL.D. W. S. W. Ruschenberger, M.D., U. S. N.

Treasurer.
Caspar Wister, M.D.

Recording Secretary.
William B. Atkinson, M.D.

Foreign Corresponding Secretary.
Richard J. Dunglison, M.D.

Home Corresponding Secretary.
Daniel G. Brinton, M.D.

It was at this time also decided that the Congress should meet in September, instead of in July, as originally suggested, and that it should continue in session for at least six days. It was, moreover, proposed that the mornings should be devoted to business and to the reading of discourses upon topics of general interest, and that in the afternoons the Congress should meet in Sections for the discussion of scientific questions.[1] After much discussion, it was determined that there should be nine Sections, as follows: (1) A Section on Medicine; (2) A Section on Biology; (3) A Section on Surgery; (4) A Section on Dermatology and Syphilography; (5) A Section on Obstetrics; (6) A Section on Ophthalmology; (7) A Section on Otology; (8) A Section on Sanitary Science; and (9) A Section on Mental Diseases. The Commission further decided that the Sections should meet on Monday, Tuesday, Wednesday, Thursday, and Friday afternoons of the week during which the Congress should be in session; that, on four of these afternoons, the deliberations of each Section should be opened by the reading of a paper upon a subject of scientific interest, by a gentleman specially chosen for that purpose, and that the paper should afterwards be submitted for discussion. The remaining afternoon was to be left free for the reception of voluntary papers. The elaboration of this plan, together with the choice of subjects to be discussed, was left to special committees.

At the meeting of the Commission which was held on the 19th of April, 1875, another and a successful effort was made to secure the co-operation of the other medical societies of the city, all of which appointed committees to

[1] The subjects finally chosen for the discourses, with the names of the gentlemen selected to deliver them, were as follows: 1. Medicine and Medical Progress, Dr. Austin Flint, of New York; 2. Surgery, Dr. Paul F. Eve, of Tennessee; 3. Obstetrics, Dr. Theophilus Parvin, of Indiana; 4. Therapeutics, Dr. Alfred Stillé, of Pennsylvania (declined); 5. Medical Jurisprudence, Dr. Stanford E. Chaillé, of Louisiana; 6. Medical Biography, Dr. Joseph M. Toner, of the District of Columbia; 7. Medical Institutions and Education, Dr. N. S. Davis, of Illinois; 8. Medical Literature, Dr. L. P. Yandell, of Kentucky; 9. Hygiene and Social Science, Dr. H. I. Bowditch, of Massachusetts; 10. Mental Hygiene, Dr. John P. Gray, of New York; and 11. Medical Chemistry, Dr. Theo. G. Wormley, of Ohio.

confer with the Commission. From this time until the meeting of the Congress, the project had the warmest support and sympathy of the whole body of the profession in Philadelphia.

The addition of so large a number of new members to the Commission, rendered that body rather unwieldy for the transaction of business, and a Committee of Conference, consisting of members from the various delegations, was therefore chosen for the purpose of harmonizing, as far as possible, different views. This Committee, after a thorough review of the work previously done by the Commission, reported that it would be inexpedient to make any material change in the plan already adopted. It recommended, however, in view of the large amount of labor likely to be imposed upon the secretaries, that two additional secretaries should be appointed. At the subsequent meeting of the Commission, Drs. WILLIAM GOODELL and ROBERT M. BERTOLET were chosen to fill these positions, all the other officers being re-elected by acclamation.

The Committee of Conference having done its work very satisfactorily, it was thought well by the Commission that thenceforward the perfecting of the plan of the Congress should be confided to a COMMITTEE OF ARRANGEMENTS,[1] consisting of the following gentlemen, who were chosen chiefly on account of the interest which they had shown in the project: Drs. S. D. Gross, Edward Hartshorne, Washington L. Atlee, Albert Fricke, Laurence Turnbull, W. W. Keen, I. Minis Hays, J. Solis Cohen, N. L. Hatfield, A. K. Minich, Thomas Geo. Morton, George Strawbridge, William Goodell, John S. Parry, R. G. Curtin, John H. Packard, James H. Hutchinson, Louis A. Duhring, Alfred Stillé, William Thomson, and Daniel G. Brinton. Prof. Gross was chairman of this Committee, and Dr. Wm. B. Atkinson acted as its secretary for the greater part of the time during which it was in existence. The meetings of the Commission were after the appointment of this Committee very infrequent; the larger body being called together only to decide questions of special importance.

A large and influential EXECUTIVE COMMITTEE was also formed about this time, and bore upon its roll the names of many of the most eminent men of the profession in various parts of the Union.

In order to secure as full a representation from foreign lands as possible, a COMMITTEE OF INVITATION was soon after appointed, to which was entrusted the duty of selecting the medical societies abroad, which should be requested to send delegates to the Congress, and also of designating the individual members of the profession, both in this and other countries, who, by the eminence which they had attained in medical science, were entitled to the compliment of a special invitation. A large number of such invitations was sent, and those to gentlemen in this country were with very few exceptions accepted. Unfor-

[1] Beside this Committee, two other Committees were appointed at this time, viz., (1) A Committee of Finance, whose duty it was to collect funds for the entertainment of the delegates; and (2) A Committee of Publication. The first Committee consisted of Drs. Caspar Wister, H. Lenox Hodge, Levi Curtis, Thomas Geo. Morton, T. Hewson Bache, Albert H. Smith, James Tyson, and Charles H. Burnett. The second Committee was never called together, and the selection of a Committee of Publication was thus left for the action of the Congress when it should assemble.

tunately, the loss of time and the great expense involved in a journey to America, prevented as many of our foreign brethren from entertaining the idea of attending the Congress as had been hoped; but the letters which they sent in answer, courteously acknowledged the compliment offered, and were expressive of the regret felt by the writers in being obliged to decline the invitation.[1]

In addition to the members specially invited, in our own country, it was finally agreed that delegates to the Congress should be received from the following bodies: (1) The American Medical Association, one delegate for every State and Territory in the Union; (2) The Association of Medical Superintendents of American Institutions for the Insane, twenty delegates; (3) The State Medical Societies, each as many delegates as its State had representatives in the Congress of the United States; (4) The Medical Staff of the Army, two delegates; (5) The Medical Staff of the Navy, two delegates; (6) The Marine Hospital Service, two delegates; (7) The American Public-Health Association, five delegates; and (8) The American Association for the Cure of Inebriates, two delegates. All the members of the Centennial Medical Commission, including members of the Executive Committee, were considered delegates by virtue of their position in the Commission.

The manner in which the officers of the Congress should be chosen, gave rise to some discussion in the Commission, some of the members holding that it would be a graceful compliment to bestow the Presidency upon a distinguished foreigner; but on the other hand, it was contended that it would be better to allow the Congress to select its own officers, and this view at length prevailed. It was made the duty of the President of the Commission to call the Congress to order when it should first meet, and, after welcoming the delegates, to appoint a Committee of Nominations, consisting of delegates from all parts of the world.

It is, perhaps, needless to add, in concluding this short sketch of the labors of The Centennial Medical Commission of Philadelphia, and of its Committees, that no pains were spared to render the visit of the delegates to the Congress a pleasant one, and that there is every reason to believe that the effort was not unsuccessful.

[1] An invitation was sent by the Commission, in September, 1875, to the International Medical Congress, then in session at Brussels, to hold its next meeting in Philadelphia. While this invitation was courteously declined, the Congress adjourned over until the year 1877, in order to give all its members, who might wish to do so, an opportunity to attend the sessions of the Centennial Congress in this country.

OFFICERS OF THE CONGRESS.

PRESIDENT.

SAMUEL D. GROSS, M.D., LL.D., D.C.L. OXON.,
OF PHILADELPHIA.

VICE-PRESIDENTS.

PAUL F. EVE, M.D., Tennessee.
W. L. ATLEE, M.D., Pennsylvania.
T. G. RICHARDSON, M.D., Louisiana.
JAMES P. WHITE, M.D., New York.
NATHAN R. SMITH, M.D., Maryland.
J. M. TONER, M.D., Dist. of Columbia.
J. B. JOHNSON, M.D., Missouri.
HUNTER MCGUIRE, M.D., Virginia.
HENRY GIBBONS, M.D., California.
GEORGE L. COLLINS, M.D., Rhode Island.
NATHAN S. DAVIS, M.D., Illinois.
LOUIS A. DUGAS, M.D., Georgia.
JOLLIFFE TUFNELL, F.R.C.S., Ireland.
C. LANGE, M.D., Denmark.
WILLIAM H. HINGSTON, M.D., Canada.
H. MIYAKE, M.D., Japan.
MICHAEL RUDNEW, M.D., Russia.
PROF. HUETER, M.D., Germany.
FREDERICK SEMELEDER, M.D., Austria.
JOHAN HJORT, M.D., Norway.
R. F. HUDSON, M.D., Australia.
PIERRE DEBAISIEUX, M.D., Belgium.
WILLIAM ADAMS, F.R.C.S., England.
ALEXANDER R. SIMPSON, M.D., Scotland.
J. K. BARTLETT, M.D., Wisconsin.

HONORARY VICE-PRESIDENTS.

JOSEPH K. BARNES, M.D.,
SURGEON-GENERAL U. S. ARMY.

JOSEPH BEALE, M.D.,
SURGEON-GENERAL U. S. NAVY.

TREASURER.

CASPAR WISTER, M.D.,
OF PHILADELPHIA.

SECRETARY-GENERAL.

I. MINIS HAYS, M.D.,
OF PHILADELPHIA.

SECRETARIES OF THE MEETING.

WILLIAM B. ATKINSON, M.D.
RICHARD J. DUNGLISON, M.D.
RICHARD A. CLEEMANN, M.D.
WILLIAM W. KEEN, M.D.
R. M. BERTOLET, M.D.

COMMITTEE OF PUBLICATION.

John Ashhurst, Jr., M.D.
Richard J. Dunglison, M.D.
William Goodell, M.D.
James H. Hutchinson, M.D.
Caspar Wister, M.D.

JOHN ASHHURST, Jr., M.D.,
Chairman, and Editor of the Transactions.

OFFICERS OF THE SECTIONS.

SECTION ON MEDICINE.

PRESIDENT.

Alfred Stillé, M.D., LL.D.,
of Philadelphia.

VICE-PRESIDENTS.

R. P. Howard, M.D.,
of Montreal.

J. J. Woodward, M.D.,
U. S. Army.

SECRETARY.

J. Ewing Mears, M.D.,
of Philadelphia.

SECTION ON BIOLOGY.

PRESIDENT.

John C. Dalton, M.D.,
of New York.

VICE-PRESIDENTS.

Austin Flint, Jr., M.D.,
of New York.

Francis W. Campbell, M.D.,
of Montreal.

SECRETARY.

James Tyson, M.D.,
of Philadelphia.

SECTION ON SURGERY.

PRESIDENT.

Joseph Lister, F.R.S.,
of Edinburgh.

VICE-PRESIDENTS.

J. A. Grant, M.D.,
of Ottawa.

John Ashhurst, Jr., M.D.,
of Philadelphia.

SECRETARY.

John H. Packard, M.D.,
of Philadelphia.

SECTION ON DERMATOLOGY AND SYPHILOGRAPHY.

PRESIDENT.

James C. White, M.D.,
of Boston.

VICE-PRESIDENTS.

S. Englested, M.D.,
of Copenhagen.

Edward Shippen, M.D.,
U. S. Navy.

SECRETARY.

Arthur Van Harlingen, M.D.,
of Philadelphia.

SECTION ON OBSTETRICS.

PRESIDENT.

Robert Barnes, M.D.,
of London.

VICE-PRESIDENTS.

Alexander R. Simpson, M.D.,
of Edinburgh.

William H. Byford, M.D.,
of Chicago.

SECRETARY.

William Goodell, M.D.,
of Philadelphia.

SECTION ON OPHTHALMOLOGY.

PRESIDENT.

R. Brudenell Carter, F.R.C.S.,
of London.

VICE-PRESIDENTS.

William Thomson, M.D.,
of Philadelphia.

Henry W. Williams, M.D.,
of Boston.

SECRETARY.

John Green, M.D.,
of St. Louis.

SECTION ON OTOLOGY.

PRESIDENT.

Clarence J. Blake, M.D.,
of Boston.

VICE-PRESIDENT.

Albert H. Buck, M.D.,
of New York.

SECRETARY.

H. N. Spencer, M.D.,
of St. Louis.

SECTION ON SANITARY SCIENCE.

PRESIDENT.

Stephen Smith, M.D.,
of New York.

VICE-PRESIDENT.

John S. Billings, M.D.,
U. S. Army.

SECRETARY.

Ezra M. Hunt, M.D.,
of Metuchen, New Jersey.

SECTION ON MENTAL DISEASES.

PRESIDENT.

John P. Gray, M.D., LL.D.,
of New York.

VICE-PRESIDENTS.

E. Grissom, M.D.,
of North Carolina.

Isaac Ray, M.D.,
of Philadelphia.

SECRETARY.

Walter Kempster, M.D.,
of Winnebago, Wisconsin.

LIST OF DELEGATES AND INVITED MEMBERS,

REGISTERED DURING THE MEETING OF THE CONGRESS.

NAME.	DELEGATE FROM
O. D. Abbott, M.D., Manchester, N. H.	State Medical Society.
William Adams, F.R.C.S., London, England.	Medical Society of London.
C. R. Agnew, M.D., New York, N. Y.	State Medical Society.
D. Hayes Agnew, M.D., Philadelphia, Pa.	Centennial Commission.
Harrison Allen, M.D., Philadelphia, Pa.	Centennial Commission.
J. W. Anawalt, M.D., Greensburg, Pa.	State Medical Society.
William Anderson, M.D., Indiana, Pa.	State Medical Society.
Abram B. Arnold, M.D., Baltimore, Md.	Medical and Chirurgical Faculty of Maryland.
John Ashhurst, Jr., M.D., Philadelphia, Pa.	Centennial Commission.
Wm. B. Atkinson, M.D., Philadelphia, Pa.	Centennial Commission.
John L. Atlee, M.D., Lancaster, Pa.	State Medical Society.
Washington L. Atlee, M.D., Philadelphia, Pa.	Centennial Commission.
H. P. Ayres, M.D., Fort Wayne, Indiana.	State Medical Society.
Francis Bacon, M.D., New Haven, Conn.	American Medical Association.
Henry T. Bahnson, M.D., Salem, N. C.	State Medical Society.
William H. Bailey, M.D., Albany, N. Y.	State Medical Society.
Henry B. Baker, M.D., Lansing, Mich.	State Medical Society.
A. S. Baldwin, M.D., Jacksonville, Fla.	State Medical Society.
Fordyce Barker, M.D., New York, N. Y.	State Medical Society.
John Barker, M.D., Dublin, Ireland.	Surgical Society of Ireland.
Robert Barnes, M.D., F.R.C.P., London, England.	Royal Medical and Chirurgical Society, and Obstetrical Society of London.

ADDRESS OF WELCOME.

BY

S. D. GROSS, M.D., LL.D., D.C.L. Oxon.,
PRESIDENT OF THE CENTENNIAL MEDICAL COMMISSION.

Gentlemen of the International Medical Congress:—

My colleagues have confided to me, as President of the Centennial Medical Commission, the agreeable and honorable duty of opening this International Medical Congress, so long the object of their solicitude and earnest labor. In their name, then, as well as in my own and in that of the entire American medical profession, whose great heart this day throbs in unison with ours, I extend to you the right hand, and bid you a thrice cordial welcome to the "City of Brotherly Love." The occasion which has brought us together this morning is one of no ordinary kind; it is one also which has been long and, I may add, anxiously anticipated. It might, perhaps, seem ungracious if I were to tell you how much time and labor have been bestowed by the Commission, through its Committee of Arrangements, upon the organization of the Congress; how often it has met to devise plans and interchange views; how earnestly and thoughtfully it has performed its work; in a word, how faithfully and conscientiously it has discharged the great trust confided to it by the different medical bodies of the city and county of Philadelphia, in which, nearly two years ago, the Congress originated. Not a little embarrassment has often attended our progress; and it has, therefore, not been without a profound sense of relief, such as a weary traveller may be supposed to experience at the end of a long and tedious journey, that at length we have found that our task has been brought to a successful close. If the organization is less complete than to some of you it may seem to be, no blame will, I am sure, be ascribed to the Commission on account of any shortcomings. There might, possibly, have been wiser and more experienced heads at work; but warmer hearts, or more conscientious men, never were, I venture to affirm, engaged in a noble enterprise. Such, then, as the work is, we cordially submit it to your consideration, satisfied that it will be accepted by you in the same kindly spirit in which it is tendered, and that any deficiencies which may mar its character will be duly rectified by your superior wisdom.

It is at all times a source of gratification to welcome friends, especially when they are united by the bonds of a common brotherhood; but on this occasion, so pregnant with important events, the feeling is vastly heightened by the fact that we have assembled around us brethren not only from every section of this great continent, but from various foreign climes—from the British Dominion, from England, Ireland, and Scotland, from France, Belgium, and Germany, from Russia, Sweden, Norway, and Finland, from Greece, from China and

Japan, from Australia, from Mexico and South America, and, I had almost said, from every country in the world. It is interesting to know that some of these delegates come here accredited by their respective governments. The invitations sent out by the Commission covered every prominent medical society and every distinguished medical man in the four quarters of the globe. The object was to bring together representative men from all nationalities to participate in our proceedings, and to afford us the benefits of their wisdom, and the results of their experience and scientific investigations. If all these, or even a respectable minority of these, representative men could have been here, what a glorious spectacle would be presented in this hall this morning! Men laying aside for a while their ordinary pursuits, crossing vast continents and perilous seas, congregating to unite with us in celebrating our first Medical Centennial, in interchanging cordial salutations, in deliberating upon the best means of promoting the dearest and holiest interests of our profession, and in laying their contributions, the accumulations of years of study and observation, upon a common altar for the common good! In its wide range, the present Congress is without a parallel. Similar bodies have repeatedly met, but none on so grand a scale, or with such a cosmopolitan outlook.

In organizing the Congress, the Commission may have been guilty of undue partiality towards its own country; and yet, perhaps, such a tendency was, after all, only natural. However this may be, certain members felt an irresistible desire to show the world what the country, since the establishment of our independence as a free and sovereign people, had accomplished for scientific medicine. For this purpose, topics illustrative of the progress and present condition of the different branches of medicine in the United States, have been assigned, as subjects for addresses, to gentlemen of acknowledged rank in the profession in different sections of the Union. These exercises will, it is believed, add greatly to the interest of the occasion. Time was, and that not at all remote, when we had no medical literature—no medical science—and but few medical schools—when we were utterly helpless, and wholly dependent upon the aid derived from our European brethren, especially the English, whose language, practice, and habits, we naturally made our own. The poverty of the country, in these respects, cannot be better illustrated than by the fact that we had no native works on medicine and the collateral sciences until after the commencement of the present century. Many of you will recall the words of the great English lexicographer who, in 1769, in speaking to a friend of the American colonies, exclaimed: "Sir, they are a race of convicts, and ought to be thankful for anything we allow them short of hanging." The Abbé Raynal, writing in the latter part of the last century, declared that America had not yet produced a single man of genius; and the question of a celebrated English writer: "Who reads an American book, or goes to an American play, or looks at an American picture or statue?" uttered at a more recent period, is still fresh in the memory of many of the present race of men. The discourses which will be delivered before you on the progress of American Medicine, will serve to show that the profession of the United States has earned for itself an enviable reputation, and that it is fully abreast of all the other pursuits that adorn the human mind and shed lustre upon the scientific character of the nation. They will serve to show that we have passed the stage of medical provincialism, and that we stand upon a

lofty platform, to which we need not be ashamed to invite the representative men of the profession of foreign countries, however illustrious, or however advanced in the arts of civilization.

The different Sections, organized by the Commission, must speak for themselves. It is in them that the work of the Congress is mainly to be done, in them that the interchange of scientific ideas is to be perfected, and from them that the meeting is to derive its chief glory as an international body of educated and enlightened men.

It will be recollected that attempts have been made of late years, in different quarters, to establish a uniformity of scientific nomenclature, of weights, measures, and records of disease for the medical profession in all parts of the civilized world. The plan, if carried out, could not fail to advance, in an eminent degree, the interests of medical science; and I am happy to be able to state that it is proposed to discuss the subject fully in one of the Sections.

We are upon the threshold of a new centennial era. One hundred years have passed away since the grand old bell upon Independence Hall announced to the world the birth of a new nation and liberty, not only to our own citizens, but to all the peoples of the earth. The century that has just elapsed is the most wonderful in all that pertains to human progress, to discovery, to inventions, to improvements, to refinement and intellectual culture; in short, to all that exalts and ennobles human nature, in its various aspects and phases, that has been vouchsafed to man since God said "Let there be light." The science of medicine has been completely revolutionized within our day. The saying, "Old things are passed away; behold all things are become new," has literally been fulfilled. The microscope, chemical analysis, clinical observation, and experiments upon the inferior animals, are leading on the medical mind with wondrous velocity in the pursuit of knowledge, and are daily adding new facts to our stock of information far beyond what the wildest fancy could have conceived, even a third of a century ago. Dogmatism, once so dominant in the schools, has ceased to exist, and no unacknowledged theories are any longer received or entertained by the scientist. Facts, resting upon the broad basis of observation and experiment, repeated and varied in a thousand ways, alone are relied upon as worthy of acceptance and as safe guides in practice. Hippocratic medicine is the order of the day. Everything bows before its divine behests.

In every corner of the habitable globe, penetrated by the light of civilization, busy, active minds, endowed with high culture and actuated by the noblest resolves, are at work, exploring the mysteries of disease, and devising means or methods of treatment for the relief of suffering, and the prolongation of life. The busy bee was never more industriously engaged in gathering honey from the flower of the field than the modern physician is in gathering knowledge at the bedside of the sick, and garnering it for future use. Much of what is considered by many as established, must be reviewed in the light of modern science; new avenues must be opened; and the ball, composed of myriads of threads more delicately formed than any ever spun by Penelope, must be pushed onward and upward by the united efforts of the medical profession in all parts of the world. How far the Centennial International Medical Congress shall promote these desirable objects, time alone can determine. It may safely be predicted that, if it do not fulfil all the promises of hope that are expected from it, it will at all

events accomplish a vast deal of useful work, and thus afford the world an earnest of its interest in the advancement of scientific medicine, and in international unity and kindly feeling. Science can have no higher mission than that of strengthening the bonds and securing the co-operation of its votaries in various portions of the globe, assembled to deliberate upon everything calculated to promote its holiest interests.

Among the many objects of an International Congress, not the least is the interchange of kindly feelings on the part of its members, the formation of new friendships, and the cementing of old ties. It is well that men of different nationalities should occasionally come together, to look at one another, to shake hands, and to see how they stand in public estimation, as well as in their own; what the world thinks of them, and what they think of the world; what they have done to further the interests of scientific progress, to lighten the burdens of human suffering, and to extend the boundaries of human happiness. All these and many other things, which need not to be here specified, are objects well worthy of engaging earnest attention on such an occasion as this.

It has often occurred to me that, if these international reunions were more frequent and more largely attended, they would be a vast deal more serviceable in preventing war and international misunderstandings than any arbitrations that could be inaugurated for the settlement of international difficulties. Much of the pleasant feeling at present existing between the United States and Europe is due to the enlarged intercourse which has been going on since the establishment of steam navigation between the two countries, and the consequent interchange of hospitality and courtesy on the part of their citizens. It is, therefore, to be hoped that this may be only one of many such reunions on this side of the Atlantic.

It needs hardly to be stated that the medical profession and the citizens of Philadelphia will do all that they can to make your time pass pleasantly, as well as profitably, during your sojourn among us. Cards of invitation will be issued to you to inspect the various institutions of interest in and around the city; and, after the work of the Congress is over, the International Exposition will no doubt claim, as it assuredly deserves, the earnest attention of every member of this body. And now that the labor of the Centennial Medical Commission is completed, it only remains for the Congress, which I now declare open, to perfect its organization by the election of officers for its own government. To facilitate this object the Commission has appointed a committee on nominations, consisting of thirteen members, nine American and four foreign, whose duty it will be to report the result of their deliberations at the earliest possible moment this morning.

MINUTES.

THE Congress assembled at noon of Monday, September 4, 1876, in the Chapel of the University of Pennsylvania. Dr. SAMUEL D. GROSS, President of the Centennial Medical Commission, called the Congress to order, and introduced the Right Reverend WILLIAM BACON STEVENS, D.D., LL.D., Bishop of the Protestant Episcopal Church in the Diocese of Pennsylvania, who opened the session with prayer. Dr. W. S. W. RUSCHENBERGER, U. S. N., one of the Vice-Presidents of the Centennial Medical Commission, having been then called to the Chair, Dr. Gross read an Address of Welcome (see page xxxiii.), after which he announced the appointment of the following Committee of Nomination:—William Adams, Esq., of England; Prof. Engelsted, of Denmark; Prof. Hueter, of Germany; Prof. Rudnew, of Russia; Dr. J. A. Grant, of Canada; Dr. H. I. Bowditch, of Massachusetts; Prof. L. A. Dugas, of Georgia; Prof. J. T. Hodgen, of Missouri; Prof. Christopher Johnston, of Maryland; Prof. Austin Flint, of New York; Dr. W. S. W. Ruschenberger, U. S. Navy; Dr. J. R. Smith, U. S. Army; Dr. Edwin M. Snow, of Rhode Island.

Dr. AUSTIN FLINT, of New York, then delivered an Address on Medicine and Medical Progress in the United States (see page 1).

The Committee of Nominations presented the following partial report of nominations for Officers of the Congress:—

President—Dr. S. D. Gross, Philadelphia.

Vice-Presidents—Dr. Paul F. Eve, Tennessee; Jolliffe Tufnell, Esq., Ireland; Dr. W. L. Atlee, Pennsylvania; Dr. C. Lange, Denmark; Dr. T. G. Richardson, Louisiana; Dr. W. H. Hingston, Canada; Dr. J. P. White, New York; Dr. H. Miyake, Japan; Dr. N. R. Smith, Maryland; Dr. M. Rudnew, Russia; Dr. J. M. Toner, District of Columbia; Dr. Hueter, Germany; Dr. J. B. Johnson, Missouri; Dr. F. Semeleder, Austria; Dr. Hunter McGuire, Virginia; Dr. Johan Hjort, Norway; Dr. G. L. Collins, Rhode Island; Dr. R. F. Hudson, Australia; Dr. H. Gibbons, California; Dr. Pierre De Baisieux, Belgium; Dr. N. S. Davis, Illinois; William Adams, Esq., England; Dr. L. A. Dugas, Georgia; Dr. A. R. Simpson, Scotland; Dr. J. K. Bartlett, Wisconsin.

Honorary Vice-Presidents—Dr. Joseph K. Barnes, Surgeon-General U. S. A.; Dr. Joseph Beale, Surgeon-General U. S. N.

Secretary-General—Dr. I. Minis Hays, Philadelphia.

Secretaries of Meeting—Drs. William B. Atkinson, R. J. Dunglison, R. A. Cleemann, W. W. Keen, R. M. Bertolet.

Section on Medicine—President, Dr. Alfred Stillé, Philadelphia; Secretary, Dr. J. Ewing Mears, Philadelphia.

Section on Biology—President, Dr. J. C. Dalton, New York; Secretary, Dr. James Tyson, Philadelphia.

Section on Surgery—President, Joseph Lister, Esq., Edinburgh; Secretary, Dr. J. H. Packard, Philadelphia.

Section on Dermatology and Syphilography—President, Dr. J. C. White, Boston; Secretary, Dr. A. Van Harlingen, Philadelphia.

Section on Obstetrics—President, Dr. Robert Barnes, London; Secretary, Dr. William Goodell, Philadelphia.

Section on Ophthalmology—President, R. Brudenell Carter, Esq., London; Secretary, Dr. John Green, St. Louis.

Section on Otology—President, Dr. L. Turnbull, Philadelphia; Secretary, Dr. H. N. Spencer, St. Louis.

Section on Sanitary Science—President, Dr. Stephen Smith, New York; Secretary, Dr. E. M. Hunt, New Jersey.
Section on Mental Diseases—President, Dr. J. P. Gray, Utica; Secretary, Dr. W. Kempster, Wisconsin.

The report was accepted, and the nominations confirmed.

Dr. GROSS then assumed the chair as President of the Congress. He thanked that body for the honor conferred upon him, and said that no other would be dearer to him during the remainder of his life than that of presiding over its deliberations. He considered it not solely an honor bestowed on him, but a tribute to the profession of Philadelphia, which had been instrumental in organizing this Congress.

On motion the Congress then adjourned until Tuesday at 10 A. M.

SECOND DAY'S SESSION.

The President called the Congress to order at 10 A. M. The minutes of the preceding day were read and approved. The Secretary-General presented a list of nearly three hundred delegates who had been registered up to this date.

Reports were then received from the various Sections, and, on motion, the conclusions adopted by them, after debate upon the topics assigned for discussion, were taken up *seriatim*, and adopted by the Congress, as follows:—

From the SECTION ON MEDICINE:—The Section considered the question, "Typho-Malarial Fever; is it a Special Type of Fever?" The debate was opened by J. J. WOODWARD, M.D., Surgeon U. S. A., and the following conclusion was adopted by the Section:—

Typho-malarial fever is not a special or distinct type of disease, but the term may be conveniently applied to the compound forms of fever which result from the combined influence of the causes of the malarial fevers and of typhoid fever.

From the SECTION ON DERMATOLOGY AND SYPHILOGRAPHY:—The consideration of the subject, "Variations in Type and in Prevalence of Diseases of the Skin in different countries of equal civilization," was introduced by JAMES C. WHITE, M.D., of Boston, and the following conclusions were adopted:—

1. Certain obscure affections, the etiology of which is little if at all understood, even in those parts of Europe to which they are mostly confined, may be regarded as practically non-existent among us—such are *prurigo*, *pellagra*, and *lichen exudativus ruber*.
2. Certain diseases, directly connected with and dependent upon poverty and habits of personal uncleanliness, are less prevalent in the United States than in those parts of Europe of which we have sufficient statistical information for comparison. Examples of this class are the *animal parasitic affections* especially.
3. Some cutaneous affections of grave character, which are dependent upon or a part of serious constitutional disorders, are of less frequent occurrence and of milder type amongst us than in Europe in general, or those parts of it where they are endemic. *Lupus*, the *syphilodermata*, and *leprosy* are the most marked instances of this class.
4. Certain disorders of the skin, especially those of its glandular system, and those connected more immediately with its nervous system, are apparently more prevalent with us than in Europe. The most notable examples of the former are *seborrhœa*, *acne*, and possibly the heat rashes; of the latter, *herpes*, *urticaria*, and *pruritus*.

In addition to the above-mentioned conclusions, the following additional proposition was adopted by the Section:—

5. The type of certain acute congestive and nervous diseases of the skin is more severe in this country than abroad.

From the SECTION ON OPHTHALMOLOGY:—A discussion on "The Comparative Value of Caustics and Astringents in the Treatment of Diseases of the Conjunctiva, and the best mode of applying them," was introduced by HENRY W. WILLIAMS, M.D., of Boston, and the following conclusions were adopted by the Section:—

1. In a considerable number of essentially transient affections of the conjunctiva, and in pterygium or other growths, no active treatment by caustics or astringents is required.
2. When disease affects only a limited portion of the conjunctiva, as in phlyctenular inflammation, the mildest stimulating or astringent remedies are usually sufficient.

3. In the acute and chronic forms of general conjunctivitis, astringents are, as a rule, safer as well as more efficacious than caustics, and are therefore better adapted to the requirements of the general practitioner.

From the SECTION ON OTOLOGY:—The subject of the "Importance of Treatment of Aural Diseases in their early stages, especially when arising from the Exanthemata," was presented by Dr. ALBERT H. BUCK, of New York, and the following conclusions were adopted by the Section:—

1. Chronic Otorrhœa is at the present time a very common disease, due in most cases to the want of proper treatment during the acute stage of the affection.
2. It is by no means a harmless affection.
3. It may be fairly classed as a preventable disease; at least among those who possess a healthy constitution.
4. Paracentesis of the membrana tympani, if resorted to during the first few days of the acute attack, and if not carried out too timidly, *i. e.*, if a free incision be made and not a mere prick, is almost a sure preventive of the subsequent chronic disease.
5. The profession at large, and especially the medical schools, should give the subject more earnest thought than they have in the past.

From the SECTION ON SANITARY SCIENCE:—"The Present Condition of the Evidence concerning Disease-germs," was reported upon by Dr. THOMAS E. SATTERTHWAITE, of New York, and the following conclusions were adopted:—

1. As far as inquiry has been made as to the results of the active principles in infective diseases, it is probable that in a certain number the matter is particulate or molecular in form, and, in the instances named, in no sense a soluble substance.
2. In regard to the causes of septicæmia, pyæmia, puerperal fever, erysipelas, and hospital gangrene, and of cholera, smallpox, the carbuncular diseases of men and animals, typhoid and relapsing fevers, and diphtheria, there is not satisfactory proof that they are necessarily connected with minute vegetable organisms.
3. The real nature of these causes is still uncertain.

Dr. LAURENCE TURNBULL, of Philadelphia, announced that, with a desire to give the posts of honor to gentlemen from a distance, he had resigned the position of President of the Section on Otology, and that Dr. CLARENCE J. BLAKE, of Boston, had been chosen by the Section to preside over its deliberations.

Dr. T. G. RICHARDSON, of New Orleans, moved that the Congress should hold itself in no way responsible for the conclusions adopted by the Sections, but that the whole responsibility in the matter should rest with the Sections themselves.

On motion of Dr. N. S. DAVIS, of Chicago, this resolution was amended, so that, upon the submission of the reports of the Sections to the Congress, the question should be merely upon their acceptance and reference for publication.

On motion of Dr. WILLIAM BRODIE, of Michigan, the previous action of the Congress in adopting the conclusions reported by the several Sections, was reconsidered, and the reports accepted and referred to the Committee of Publication.

The Secretary-General then read letters of greeting from the IMPERIAL SOCIETY OF ST. PETERSBURG, Russia, and from the UNIVERSITY OF CHRISTIANIA, Norway. He also read the following letter from Dr. J. S. BILLINGS, U. S. Army:—

WAR DEPARTMENT, SURGEON-GENERAL'S OFFICE,
WASHINGTON, D. C., July 31, 1876.

SIR: By direction of the Surgeon-General, U. S. Army, I have the honor to forward herewith to your address six (6) copies of a specimen fasciculus of a catalogue of the library of this office, and to request that they may be presented to the International Medical Congress. While the object in view in forming this library has been to make a collection of sufficient extent and completeness to meet the wants of the physicians of the United States, an attempt is being made to prepare a catalogue and index of its contents, whose practical usefulness shall not be confined to this country, but shall be, as far as the material

available will permit, international and cosmopolitan. The manuscript of the entire work is so nearly completed that the printing can be commenced next spring if Congress shall see fit to give the necessary authority.

Very respectfully, your obd't servant,

JOHN S. BILLINGS,
Assist. Surgeon U. S. Army, in charge of Library.

Whereupon Dr. AUSTIN FLINT, of New York, offered the following preamble and resolutions, which were adopted:—

Whereas, The institution of a National Library containing all the important bibliographical and periodical publications relating to medicine and the collateral sciences, in the past and present time, is of importance, not alone to the medical profession, but to persons in other pursuits who may desire to refer to works treating of topics embraced in these departments of knowledge, and also concerns greatly the public welfare in so far as this is involved in the elevation of the standard of medical education; and

Whereas, Through the wisdom of the National Legislators of the United States Government, a medical library has been established, containing, at the present time, about 40,000 volumes, and about the same number of single pamphlets; and

Whereas, Experience has already shown the practical advantages of the present library, and, at the same time, the great need of its being made more complete by increasing at least tenfold the number of publications which it now contains; and

Whereas, In order to render such a library available for reference, especially to medical men and others residing at a distance, a catalogue wherein publications are classified after the names of authors and subjects, the scope of each publication being stated, is indispensable; and

Whereas, Such a catalogue of the National Medical Library has been prepared under the direction of the Surgeon-General of the United States Army by Assistant Surgeon J. S. Billings, copies of a specimen fasciculus having been forwarded for examination by the members of the International Medical Congress; therefore,

Resolved, First. That the members of this International Medical Congress regard with great interest the institution of a National Medical Library in the City of Washington, and respectfully petition the Congress of the United States to provide for additions to the number of volumes and periodical publications, until the library is made as complete as possible.

Second. That in view of the necessity of what is known as a *Catalogue raisonné*, in order to render the library properly available for reference, this International Medical Congress urges the importance of an early completion and publication of such a catalogue.

Third. That the Specimen Fasciculus of the Catalogue, which is stated to be nearly ready for the press, affords evidence of great labor and care, and the arrangements for convenience of reference it is believed will prove in all respects satisfactory.

Fourth. That those of the delegates to this International Medical Congress who are citizens of the United States, and other members of the Medical Profession in this country, are urged individually to exert their influence to secure the enlargement of the library, and the speedy publication of the Catalogue.

The Committee of Nominations then presented the following supplementary report, which was accepted, and the nominations confirmed:—

Committee of Publication (with power to choose its chairman and an editor)—Dr. John Ashhurst, Jr., Dr. Richard J. Dunglison, Dr. William Goodell, Dr. James H. Hutchinson, Dr. Caspar Wister, all of Philadelphia.

Treasurer—Dr. Caspar Wister, Philadelphia.

Vice-Presidents of the Sections.

Section on Medicine—Dr. R. P. Howard, Canada; Dr. J. J. Woodward, U. S. Army.

Section on Biology—Dr. Austin Flint, Jr., New York; Dr. F. W. Campbell, Canada.

Section on Surgery—Dr. J. A. Grant, Canada; Dr. J. Ashhurst, Jr., Philadelphia.

Section on Dermatology and Syphilography—Dr. S. Engelsted, Copenhagen; Dr. E. Shippen, U. S. Navy.

Section on Obstetrics—Dr. Alexander R. Simpson, Edinburgh; Dr. W. H. Byford, Illinois.

Section on Ophthalmology—Dr. William Thomson, Philadelphia; Dr. Henry W. Williams, Boston.

Section on Otology—Dr. A. H. Buck, New York.

Section on Sanitary Science—Dr. J. S. Billings, U. S. Army.

Section on Mental Diseases—Dr. E. Grissom, North Carolina; Dr. I. Ray, Philadelphia.

Dr. HENRY I. BOWDITCH, of Massachusetts, then read an Address on Hygiene and Preventive Medicine (see page 21), Vice-President PAUL F. EVE, of Tennessee, occupying the Chair; and afterwards Dr. THEO. G. WORMLEY, of Ohio, delivered an Address on Medical Chemistry and Toxicology (see page 49).

The Congress then adjourned until Wednesday at 10 A. M.

THIRD DAY'S SESSION.

The Congress met at 10 A. M.; the President in the Chair. The minutes of the previous day were read and approved.

On motion of Dr. JOHN L. ATLEE, of Lancaster, Pa., the Secretary was instructed to transmit copies of the Address of Dr. Bowditch, when printed, to the Governor of each State and Territory, with the request that it be transmitted to the Legislature of such State or Territory; and, on motion of Dr. TRENHOLME, of Montreal, the government of the Dominion of Canada and those of its several provinces were included in the terms of the resolution.

On motion of Dr. TRAILL GREEN, of Easton, Pa., Dr. Wormley's Address was referred to the Committee of Publication, and the name of Dr. Wormley's wife, who had assisted him in his labors, was ordered to be entered on the rolls of the Congress.

The Secretary-General reported 382 names of delegates on the register. He announced the reception of a telegram from the NATIONAL TEMPERANCE ASSOCIATION, respectfully inviting an expression of opinion from the Congress regarding the use of alcohol.

The Secretary-General also read invitations to the members of the Congress to visit the following institutions:—The Academy of Natural Sciences of Philadelphia, Dr. W. S. W. Ruschenberger, President; The University of Pennsylvania, Dr. Robert E. Rogers, Dean; The Jefferson Medical College, Dr. John B. Biddle, Dean; The Pennsylvania Hospital; The College of Physicians of Philadelphia; and The Archæological Association; and from Dr. William Pepper, Medical Director of the Centennial Exposition, extending courtesies to visiting members. These invitations were, on motion, accepted.

An invitation was also read from the Council of the National Forest Association to attend its convention about to assemble at Cape May, N. J., on September 7 and 8.

The Secretaries of Sections then reported the conclusions adopted by their several Sections as follows:—

By the SECTION ON BIOLOGY:—The consideration of "The Excretory Function of the Liver," was opened by Dr. AUSTIN FLINT, Jr., and the following conclusions were adopted:—

1. Cholesterine exists in health in the bile, blood, and nervous matter, also in the crystalline lens, the spleen, and meconium.
2. Cholesterine is formed for the most part in the nervous matter, from which it is passed into the blood. The blood gains cholesterine in its passage through the brain. Its formation is constant, and it is always found in the blood.
3. Cholesterine is separated from the blood by the liver, and discharged with the bile. It pre-exists in the blood, serves there no useful purpose, and, if allowed to accumulate, blood poisoning results.
4. The bile has two separate and distinct functions, one connected with nutrition, to which the so-called biliary salts, glycocholate and taurocholate of soda, contribute; these do not exist preformed in the blood, but are products of *secretion*. The second function of the bile is *excretory*, connected with depuration or excretion; this is accomplished by the removal of the cholesterine which it obtains from the blood.
5. Normal feces do not contain cholesterine. The latter substance is represented by *stercorine*, formerly called *séroline*, into which it is converted in its passage down the intestine. The conversion of cholesterine into stercorine does not, however, take place when digestion is arrested or when it is not necessary, as is shown by the presence of cholesterine in its own form in the feces during fasting, and in the meconium.
6. The difference between the two varieties of jaundice, one mild and the other severe,

is dependent on obstruction of the bile-ducts in one instance, with reabsorption of the biliary coloring matters, while in the other there is retention of cholesterine in the blood in consequence of destruction of the parenchyma of the liver.

7. That condition of the blood dependent upon the presence of cholesterine in the blood is called *cholesteræmia*. It is characterized by symptoms referable to the brain, and may or may not be attended with jaundice.

8. Cholesteræmia does not occur in every disorder of the liver, because, even when a part of the organ is disorganized, there may remain a part still capable of performing the functions of excreting cholesterine.

9. In cases of simple jaundice, even when fæces are decolorized, there is no accumulation of cholesterine in the blood.

10. Cholesterine bears the same relation to the liver that urea does to the kidneys.

By the SECTION ON DERMATOLOGY AND SYPHILOGRAPHY:—The debate on the question, "Are Eczema and Psoriasis Local Diseases, or are they Manifestations of Constitutional Disorders?" was opened by Dr. L. DUNCAN BULKLEY, of New York, and the following conclusions were adopted:—

1. Eczema and psoriasis are distinct diseases. The former is to be clearly distinguished from artificial dermatitis, and the latter from the eruptions of syphilis, scaly eczema, and leprosy.

2. Eczema and psoriasis cannot own a double causation or nature at one time local and at another constitutional; but, with other diseases, may have a twofold cause, a predisposing and an exciting.

3. Eczema and psoriasis in many of their features resemble the accepted constitutional diseases more than they do those recognized as local.

4. Eczema is most properly likened to catarrh of the mucous membranes; it is very probable that some attacks called catarrh are eczema and psoriasis of the mucous tissue.

5. Both eczema and psoriasis resemble gout and rheumatism in certain respects, and are dependent upon a somewhat similar, although as yet unknown, constitutional cause; much of the skin lesion must be looked upon as the local result or remains of the diseases.

6. There as yet exists no microscopical or physiological proof that eczema and psoriasis are the sole result of local cell disorder, either congenital or acquired, or due alone to perverted nerve action.

7. Local causes play a very important part in the etiology of eczema. They are probably inoperative in psoriasis.

8. Local treatment is often insufficient alone to remove the lesions of eczema and psoriasis, and cannot prevent or delay relapses; its success does not necessarily demonstrate the local nature of these affections.

9. Constitutional treatment, alone and singly, can cure many cases of eczema and psoriasis, and prevent or delay relapses in a certain proportion of cases; under constitutional treatment is included every agency not properly classed among local measures.

10. The total weight of evidence and argument is that eczema and psoriasis are both manifestations of constitutional disorders and not local diseases of the skin.

By the SECTION ON OBSTETRICS:—The discussion of "The Mechanism of Natural and of Artificial Labor in Narrow Pelves," was introduced by Dr. WILLIAM GOODELL, of Philadelphia, and the following conclusions were adopted by the Section:—

1. The unaided first-coming head and the aided after-coming head observe in a flat pelvis precisely the same general laws of engagement and of descent. Hence, version here means art *plus* nature.

2. The forceps, however applied in a flat pelvis, antagonizes more or less with the natural mechanism of labor. Hence, the forceps here means art *versus* nature.

3. The aided and the unaided first-coming head observe in a uniformly narrowed pelvis precisely the same laws of engagement and of descent. But version violates these laws. Hence, the forceps here means art *plus* nature; version, art *versus* nature.

4. At, or above, the brim of a flat pelvis, the fronto-mastoid, or even the fronto-occipital, application of the forceps interferes less with the moulding of the head, and violates the natural mechanism of labor less, than the biparietal application.

5. In the flat pelvis, the vectis aids the natural mechanism of labor, and, therefore, meets the indications better than the forceps.

By the SECTION ON MENTAL DISEASES:—The consideration of the subject of the "Responsibility of the Insane for Criminal Acts," was introduced by Dr. ISAAC RAY, of Philadelphia, and the following conclusions were adopted by the Section:—

1. There is at present a manifest tendency to hold the insane responsible for criminal acts.
2. This tendency is unjust, unphilosophical, and contrary to the teachings of pathology, which clearly point out that insanity is but the expression of disease.

The SECTION ON MEDICINE also submitted the following resolutions for the action of the Congress, and on motion of Dr. BRODIE, of Michigan, they were adopted :—

Resolved, That the International Medical Congress of 1876 recognizes the advantages which would accrue from the introduction of a gradual uniformity in the multiple and heterogeneous elements of physic, as posology, nomenclatures, etc., and in the means and records of medical observation.

Resolved, That, in consequence, this Congress authorizes the President to appoint three delegates to the International Congress of 1877, with the special mission of presenting a schedule of the means of uniformity in physic actually applicable in all countries, and another of those which could soon be made acceptable by the profession at large.

Resolved, That the said delegates be advised to invite the co-operation of the men who have already worked for the same cause at the International or National Medical or Pharmaceutical Congresses of Paris, Vienna, St. Petersburg, Brussels, and Buffalo.

Under the above resolutions, the following delegates were subsequently appointed by the President: Dr. Henry I. Bowditch, of Boston, Dr. J. J. Woodward, U. S. A., of Washington, and Dr. E. Seguin, of New York.

Dr. PAUL F. EVE, of Tennessee, then delivered an Address on Surgery (see page 73), Dr. RUDNEW, of St. Petersburg, Russia, Vice-President, occupying the Chair; after which Dr. J. M. TONER, of the District of Columbia, delivered an Address on Medical Biography (see page 91), while Dr. L. A. DUGAS, of Georgia, Vice-President, occupied the Chair.

On motion the Congress then adjourned until Thursday at 10 A.M.

[On Wednesday evening, at 7.30 P.M., Dr. J. J. WOOWARD, U. S. Army, delivered in the Lecture Room of Jefferson Medical College an Address on The Medical Staff of the United States Army, and its Scientific Work (see page 286).]

FOURTH DAY'S SESSION.

The Congress met at 10 A. M., the President in the Chair. The minutes of the previous day were read and approved. The Secretary-General reported 422 names of delegates on the Register.

Dr. H. I. BOWDITCH, of Boston, presented the following preamble and resolutions, which were adopted :—

Whereas, The work already accomplished by the officers connected with the Bureau of the Surgeon-General of the United States Army, in the establishment of a medical library, and in the preparation of its complete and unique catalogue, in the formation of an anatomical museum from which important scientific results have already been obtained, and which have been not only a source of honor to these United States, but of value to foreign lands wherever science is cultivated ; and,

Whereas, This Congress learns with regret that, owing to the lack of a sufficient clerical force and of pecuniary means, not only some of the work already in progress has been suspended, but that other work of equal value cannot be undertaken, although ample materials for the same are now lying unused in the Surgeon-General's office ; therefore,

Resolved, That a committee of three be appointed to prepare a memorial to be presented to the Congress of the United States, at the earliest day possible, at its next session, urging efficient support to these most important works.

Resolved, That it is desirable that said memorial should be signed by the President, Vice-Presidents, and Secretary-General of this body.

The President appointed Drs. Bowditch, of Boston, Rudnew, of St. Petersburg, and N. S. Davis, of Chicago, as the Committee to prepare this Memorial.

On motion of Dr. J. P. WHITE, of Buffalo, New York, it was ordered that the printed pamphlet containing Dr. Bowditch's Address on Hygiene and Preventive Medicine be sent to the Presidents of State and Territorial Medical

Societies and Sanitary Boards of the United States, and of the Societies and Sanitary Boards of the Dominion of Canada.

The conclusions adopted by the several Sections were then reported as follows:—

By the SECTION ON SURGERY:—The subject of the "Medical and Surgical Treatment of Aneurism," was introduced by Dr. WILLIAM H. VAN BUREN, of New York, and the following conclusions were adopted:—

1. Tufnell's treatment of aneurism, by rest, position, and restricted diet, offers a valuable resource in thoracic and abdominal aneurisms.
2. It should always be tried in innominate, subclavian, subclavio-axillary, and iliac aneurisms, before resorting to measures attended by risk to life.
3. For aneurisms of the subclavian and iliac arteries, the Hunterian operation, with our present means of preventing secondary hemorrhage, is not justifiable.
4. For reasons formally set forth by Holmes and Henry Lee, the "old operation" cannot properly be formally substituted for the Hunterian operation in these cases, but should be held in reserve for special cases.
5. It is the most safe and surgical resource in gluteal aneurism, if the circulation can be commanded by the hand *in recto*.
6. The mode of cure by embolism, aimed at in the method of manipulation, is a not unfrequent explanation of what is called spontaneous cure of aneurism.
7. The value of Esmarch's bandage in the treatment of aneurism is probably not fully estimated.
8. In view of the promising features presented by the cases of Levis and Bryant, in which horse-hair was introduced into an aneurismal tumor, the repetition of this operation, or the substitution for horse-hair of Lister's prepared catgut or other animal substances, may be properly tried.

By the SECTION ON DERMATOLOGY AND SYPHILOGRAPHY:—The consideration of the subject of "The Virus of Venereal Sores; its Unity or Duality," was opened by Dr. F. J. BUMSTEAD, of New York, and the following conclusions were adopted by the Section:—

1. The virus of venereal sores is dual.
2. Venereal sores may be due to the inoculation of the syphilitic virus, and also to the inoculation of products of simple inflammation.
3. These two poisons may be inoculated simultaneously.
4. (Additional.) The present state of science has demonstrated that suppurating inflammatory lesions resembling chancroids may be produced on various portions of the body by inoculation with simple pus from various lesions.

By the SECTION ON OTOLOGY:—Dr. H. N. SPENCER, of St. Louis, opened a discussion of the question, "In what Percentage of Cases do Artificial Drum-membranes prove of Practical Advantage?" The following were the conclusions adopted by the Section:—

1. Of the various forms of artificial drum-membrane in use, the cotton pellet is preferable for its greater simplicity and its easier introduction, for the greater uniformity of its effect, and the comparative safety in its employment.
2. It has an advantage over all other forms of artificial drum-membrane in that, in addition to the functional gain which may be derived, there may be added its value as a means of treating the tympanum, and this therapeutical use of the artificial membrane has a great future in otology.
3. The continued use of the artificial drum-membrane as a means of improving the hearing is indicated in rare conditions which can only be determined by the aural surgeon.

By the SECTION ON SANITARY SCIENCE:—"The General Subject of Quarantine, with Particular Reference to Cholera and Yellow Fever," was considered by Dr. J. M. WOODWORTH, of the U. S. Marine Hospital Service, and the following conclusions were adopted by the Section:—

1. The supervision of ocean travel ought to be directed to securing good sanitary conditions of vessels at all times, out of as well as in port.
2. A system of *Port Sanitation* should be adopted and administered for each country or place, separately, modified in particular cases by taking into account the liability of the port to infection, the period of incubation of the disease, the length of time consumed in the voyage, and the measures enforced by the vessel *en route*.

3. In some countries the detention of passengers and crews of ships hailing from infected ports is unwarranted, but for such time only as is necessary to complete the period of incubation of cholera or yellow fever, counting from the date of departure from an infected port, or of landing from an infected vessel; but in no instance should passengers or sailors be held for observation on board an infected vessel, and such vessel should not be detained beyond the period required for inspection and thorough disinfection and cleansing.

4. Recognizing the fact that the morbific causes of infectious diseases may sometimes elude the most vigilant sanitary supervision of shipping, the importance of wisely-directed internal sanitary measures can scarcely be over-estimated.

5. As far as America is concerned, it is desirable that prompt and authoritative information should be had of the shipment of passengers or goods from districts infected with cholera or yellow fever, thereby insuring the thorough disinfection of infected articles.

6. The endemic homes of cholera and yellow fever are the fields which give the greatest promise of satisfactory results to well-directed and energetic sanitary measures, and to this end an international sentiment should be awakened, so strong as to compel the careless and offending people to employ rational means of prevention.

By the SECTION ON MENTAL DISEASES:—The consideration of the subject of the "Simulation of Insanity by the Insane," was opened by Dr. C. H. HUGHES, of St. Louis, Mo., and the following conclusion was adopted by the Section:—

It is not only not impossible for the insane to simulate insanity for a purpose in any but its gravest forms of profound general mental involvement, but they actually do simulate acts and forms of insanity for which there exists no pathological warrant that we can discover in the real disease affecting them.

On motion of Dr. T. G. RICHARDSON, of Louisiana, Dr. J. J. WOODWARD, U. S. A., was requested to repeat his lecture of the previous evening, as many of the members had failed to read the announcement of the lecture on the Programme, and had, therefore, been absent.

Dr. THEOPHILUS PARVIN, of Indiana, then delivered an Address on Obstetrics (see page 138), Dr. H. MIYAKE, of Tokio, Japan, Vice-President, occupying the Chair, and, after a very brief recess, Dr. STANFORD E. CHAILLÉ, of Louisiana, delivered an Address on Medical Jurisprudence (see page 167), while Dr. J. P. WHITE, of Buffalo, New York, Vice-President, occupied the Chair.

The Congress then adjourned until 10 A.M. on Friday.

FIFTH DAY'S SESSION.

The Congress met at 10 A. M., the President in the Chair. The minutes of the preceding day were read and approved. The Secretary-General reported 430 names of delegates on the Register.

On motion of Dr. PAUL F. EVE, of Nashville, it was

Resolved, That no papers or addresses read before this body, and ordered to be printed, shall be furnished either in abstract or otherwise for publication in any journal prior to the publication of the Transactions.

The conclusions adopted by the several Sections were then reported as follows:—

By the SECTION ON BIOLOGY:—The consideration of "The Mechanism of Joints," was introduced by Dr. HARRISON ALLEN, of Philadelphia, and the following conclusions were adopted by the Section:—

1. Starting with the idea that joints are of dynamic and static values, it is shown that in most movable joints the ball-and-socket arrangement predominates. When the ball is supported by the socket, as at the occipito-atloid articulation, *rest* is suggested. But when the ball is suspended from the socket, as at the temporo-maxillary articulation, *motion* is suggested.

2. Articular surfaces are of three kinds: *axial, actinic*, and *lateral*. The *axial* or primary surfaces are those situated upon proximal and distal ends of a bone in the line of its longitudinal axis. The *actinic* or secondary (rarely seen) are those placed in a line which is deflected from the longitudinal axis. The *lateral* or tertiary are those situated upon the sides of the shaft or body of a bone, and serve for articulation with corresponding surfaces of other bones.

3. Axial surfaces, it is believed, are static; actinic surfaces are dynamic; while lateral

surfaces have subordinate degrees of value—some of them being adventitious. The outer femoral condyle is active in extension = static; the inner femoral condyle is active in flexion = dynamic; but the lateral facets have no independent action.

4. Joints are fixed or locked at extremes of flexion and extension, and are most relaxed at the intervals between these extremes.

5. When a facet is actively employed, it enters into a combination with which the entire limb is in harmony. Hence, in the study of any one facet, its relations to all others of its kind, as well as to the bones, muscles, and fasciæ of its limb, become essential.

6. A correct knowledge of the symptomatology and treatment of diseases of the joints is dependent upon a true conception of the complex nature of articular surfaces.

By the SECTION ON SURGERY:—Dr. LEWIS A. SAYRE, of New York, opened the discussion of the subject of the "Treatment of Coxalgia." The Section adopted the following conclusions:—

1. Morbus coxarius is a disease most frequently met with in early childhood, or the age of reckless indifference.

2. It is almost always of traumatic origin, and not necessarily connected with a vitiated constitution.

3. Rest and freedom from pressure of the parts involved, while at the same time the rest of the body is allowed free exercise in the open air, and a nutritious diet, is the best treatment that has yet been devised for this disease.

4. If this plan of treatment be adopted in the early stages of this disease, the majority of cases will recover, with nearly if not quite perfect motion, and without deformity.

5. In the advanced second stage of the disease, when absorption of the effused fluid cannot be produced, then it is better to puncture or aspirate the joint and remove its contents, than to leave it to rupture by ulceration.

6. In the third stage of the disease, when the treatment recommended in this paper has been properly applied without satisfactory improvement, but progressive caries continues, the exsection of the diseased bone is not only justifiable, but in many cases absolutely necessary.

7. That the operation of exsection of the hip is easily performed, and in itself attended with little or no danger.

8. That after exsection of the hip-joint in cases of progressive caries, the recovery is much more rapid and certain, and infinitely more perfect, as to form, motion, and the usefulness of the joint and limb, than when left to the slow process of nature.

[NOTE.—In the second conclusion, the Section does not unanimously coincide.]

By the SECTION ON DERMATOLOGY AND SYPHILOGRAPHY:—After a debate, opened by Dr. E. L. KEYES, of New York, on "The Treatment of Syphilis with special reference to the Constitutional Remedies appropriate to its various stages; the Duration of their Use, and the question of their Continuous or Intermittent Employment," the Section adopted the following:—

Negative conclusions, for which there would seem to be no foundation in fact:

1. Syphilis commencing mildly needs but little treatment, and does not require mercury.
2. Mercury given internally is necessarily debilitating.
3. Mercury is only useful in secondary syphilis.
4. Iodide of potassium is of considerable value in secondary syphilis.
5. Iodide of potassium is of no value unless preceded by the use of mercury.
6. Iodide of potassium acts by liberating mercury which has been lying latent.

Positive conclusions, which, in the present state of our knowledge, may be affirmed:

1. Mercury is an antidote to the syphilitic poison, and of service in controlling all its symptoms in all, even the latest stages of the disease; its power over gummata being least, and not to be relied upon.
2. Mercury in minute doses is a tonic.
3. Iodine cures certain symptoms of syphilis, but does not prevent relapses.
4. Mercury, long continued uninterruptedly, as far as practicable, in small doses from the time of the earliest eruption, constitutes the best treatment of syphilis.

By the SECTION ON OPHTHALMOLOGY:—A discussion on the question, "Are Progressive Myopia and Posterior Staphyloma due to Hereditary Predisposition, or can they be induced by Defects of Refraction, acting through the Influence of the Ciliary Muscle?" was opened by Dr. E. G. LORING, Jr., of New York, and the following conclusions were adopted by the Section:—

1. From the fact that so many children are myopic, whose parents are not near-sighted, while the myopia increases directly with the amount of increased tension of the eyes, and

from the fact that an interchange of refraction may occur, whereby an eye which is not congenitally myopic may become so in spite of hereditary tendency against it, it would seem to follow that hereditary predisposition, though undoubtedly a potent cause, is not only not the sole cause, but that it is not even the predominating cause.

2. The action of the ciliary muscle, taken by itself, exerts but little influence on the production of myopia, and still less on the formation of the cone.

[NOTE.—Of these conclusions, the first was adopted by the Section unanimously, and the second by a majority of fifteen to seven.]

Dr. N. S. DAVIS, of Chicago, offered the following preamble and resolutions, which were adopted :—

Whereas, This Congress marks an era in the history of medicine in the United States of America, the addresses as delivered presenting a summary of progress in the various departments which will be of great historical value in all coming time ; and

Whereas, It is highly probable that these addresses, in connection with the many very valuable papers read and discussed in the Sections, will require for their early and proper publication more funds than are at present in the hands of the Treasurer for the purpose ; therefore,

Resolved, That the Committee of Publication be authorized and instructed, as soon as practicable after the final adjournment of the Congress, to ascertain the probable cost of publishing the full Transactions in a style appropriate for the work, and, if the money on hand be found deficient, to address a circular letter to the American members of the Congress, asking for such additional sum, not exceeding $10 for each of such members, as will supply the deficiency ; and that said committee be authorized to withhold the volume or volumes, when published, from any member who may neglect to pay the additional sum required.

Resolved, That the Committee of Publication be authorized and requested to exercise a careful and liberal discretion in preparing and revising the proceedings and reported discussions in the several Sections, for publication in the Transactions of the Congress.

The Secretary General announced the receipt of communications from the Woman's National Christian Temperance Union, and from the Friends Temperance Union of New York, respectfully inviting an expression of opinion from the Congress concerning the use of alcohol.

On motion of Dr. N. S. DAVIS, these were referred to the Section on Medicine.

On motion of Dr. J. M. TONER, of Washington, D. C., the communication previously received from the National Temperance Association was similarly referred.

After a recess of ten minutes, Dr. J. P. GRAY, of Utica, N. Y., read an Address on Mental Hygiene (see page 205), Dr. HUNTER MCGUIRE, of Virginia, Vice-President, occupying the Chair; and afterwards Dr. LUNSFORD P. YANDELL, of Louisville, Kentucky, delivered an Address on Medical Literature (see page 223), while Dr. T. G. RICHARDSON, of Louisiana, Vice-President, occupied the Chair.

On motion, the various addresses read before the Congress were referred to the Committee of Publication, and the Congress then adjourned until 10 A. M. on Saturday.

SIXTH DAY'S SESSION.

The Congress met at 10 A. M., the President in the Chair. The minutes of the preceding day were read and approved. The Secretary-General reported 447 names of delegates on the register (see page xv.), and, on motion of Dr. TONER, these were all confirmed as members of the Congress.

The Secretary-General read a request from Dr. RUDNEW, of Russia, asking the privilege of access to the minutes and proceedings of the Congress, with a view of reporting them on his return to Russia, which was granted.

The Section on Medicine recommended that the Secretary be directed to send, in reply to the various Temperance Associations which had sent communications to the Congress, the following conclusions which had been approved by the Section, and which were contained in a paper read before it by

Dr. E. M. Hunt, of New Jersey, entitled "Alcohol in its Therapeutic Relations as a Food and as a Medicine."

1. Alcohol is not shown to have a definite food value by any of the methods of chemical analysis or physiological investigation.
2. Its use as a medicine is chiefly that of a cardiac stimulant, and often admits of substitution.
3. As a medicine, it is not well-fitted for self-prescription by the laity, and the medical profession is not accountable for such administration, or for the enormous evils arising therefrom.
4. The purity of alcoholic liquors is, in general, not as well assured as that of articles used for medicine should be. The various mixtures, when used as medicines, should have a definite and known composition, and should not be interchanged promiscuously.

On motion of Dr. J. P. White, of Buffalo, it was

Resolved, That the Centennial Medical Commission of Philadelphia is hereby tendered the cordial thanks of this Congress for the most excellent manner in which its members have discharged the arduous duties devolved upon them, and by which our pleasure and profit have been so much enhanced.

Resolved, That the President and other Officers of the International Medical Congress of 1876 are hereby tendered the cordial thanks of the Congress for the excellent manner in which they have discharged the arduous duties devolved upon them, and by which our pleasure and profit have been so much enhanced.

Resolved, That the Officers and Trustees of the University of Pennsylvania are hereby tendered our cordial thanks for the very liberal use of their excellent buildings for the meetings of this International Medical Congress.

Resolved, That the Officers and Trustees of the Jefferson Medical College are hereby tendered the cordial thanks of this Congress for the use of their lecture-room for the most interesting lecture of Dr. J. J. Woodward, U. S. A.

Resolved, That the cordial thanks of the International Medical Congress are especially due to Drs. Thomson, Wilson, and Strawbridge, and to Messrs. Henry C. Lea and J. B. Lippincott, for their generous hospitality.

On motion of Dr. H. I. Bowditch, of Boston, the following resolution was adopted:—

Resolved, That we, a brotherhood of physicians from the North, South, East, and West of this country, hereby tender to our associates from other lands our most earnest wishes that they may have safe and happy returns to their homes, and we would suggest the hope that they will carry back many pleasant memories of this fraternal meeting, now closing, and which has been, most appropriately, held in this generous and noble city of Philadelphia.

Dr. J. A. Grant, of Ottawa, Canada, stated that at a meeting of the members of the Canadian medical delegates, held yesterday, the following resolutions were adopted unanimously:—

Resolved, That the Canadian members of the International Medical Congress desire to express their sense of the great consideration and urbanity with which they have been treated by the officers and members of the Centennial Medical Commission, and beg, by this resolution, to tender their warm thanks for the same.

Resolved, That the Canadian members of the International Medical Congress most cordially join with the other members of the Congress in thanking the physicians and citizens of Philadelphia for the generous hospitality extended to its members throughout the present session.

Dr. Charles J. Hare, of London, read the following expression of congratulation from the delegates of Great Britain:—

The delegates from Great Britain to the International Medical Congress of Philadelphia beg to congratulate the President and the several committees on the complete success of the Congress, on the high value of the various addresses presented to it, and on the forward impulse which it has given to the progress of medicine in the widest sense of that word. They desire at the same time to express in the strongest and warmest terms their sense of and their thanks for the unmeasured kindness and courtesy and the unbounded hospitality with which they have been received on this Centennial occasion, and to add that they will carry back with them a most grateful recollection of that warm right hand of fellowship which has been so warmly extended to them by their brethren of the United States.

Signed on behalf of the British delegates by Charles J. Hare, M.D. Cantab., F.R.C.P.,

late Professor of Clinical Medicine in University College, and Physician to University College Hospital; R. BRUDENELL CARTER, F.R.C.S. Eng., Hunterian Professor of Surgery to the Royal College of Surgeons of England; WILLIAM ADAMS, F.R.C.S., President of the Medical Society of London.

Dr. L. A. SAYRE, of New York, offered the following:—

Resolved, That this International Medical Congress requests its President, Professor Samuel D. Gross, to sit for his portrait, and that the Committee of Publication be instructed to have the same engraved and printed as a frontispiece to the Volume of Transactions. Adopted.[1]

The Secretary-General stated that a circular had been received announcing that an International Medical Congress would be held in Geneva in September, 1877.

Dr. N. S. DAVIS, of Illinois, then delivered an Address on Medical Education and Medical Institutions (see page 265), Dr. HENRY GIBBONS, of California, Vice-President, occupying the Chair.

Dr. GROSS, President, announced that the official programme of the Congress had been completed. No new business being presented, he addressed the Congress as follows:—

GENTLEMEN: Before I put the question of the final adjournment of the Congress, I desire to say a few parting words. First and foremost, I must be permitted again to thank you for the great honor which you have done me in electing me as your presiding officer. It is the last honor which I can reasonably expect from my professional brethren, who have always been so kind to me in the bestowal of their favors and of their good opinion. For these courtesies I shall never cease to be grateful, for they have served to cheer me in my labors, and have been as a balm to my soul.

The International Medical Congress of 1876 is about to pass into history as a thing of the past; but, although its exercises are at an end, its work will live and form an interesting era in our profession as marking the reunion of a great body of men in the Centennial year of American Independence. We have listened to a number of valuable and instructive discourses, illustrative of the progress of American medicine and surgery; have been engaged in profitable debates affecting some of the most vital interests of society; have performed a large amount of earnest work in the Sections; have met at the festive board; have clasped hands, and have formed warm and, as I trust, lasting friendships, all without any discord, one unkind expression, or even one word of misunderstanding. Altogether, we have every reason for self-congratulation. When another Centennial century shall have passed away, the men who shall then be upon the stage will not fail to commemorate our meeting, and to bless us for what has been done this week in the interests of humanity and of medical science. In dissolving this meeting, as I now do, permit me to invoke upon our labors the choicest blessings of Almighty God, and to wish each and all of you a safe return to your homes, and a happy reunion with your families and friends. May we not hope that you may long, if not forever, retain pleasant memories of our meetings in this Chapel, and that in your leisure moments your minds may occasionally revert to those of us from whom you are about to separate?

The Congress then adjourned *sine die*.

I. MINIS HAYS, M.D.,
Secretary-General.

WILLIAM B. ATKINSON, M.D.,
RICHARD J. DUNGLISON, M.D.,
RICHARD A. CLEEMANN, M.D.,
WILLIAM W. KEEN, M.D.,
R. M. BERTOLET, M.D.,
Secretaries of the meeting.

[1] [In deference to Prof. Gross's expressed wish, the portrait is omitted.—EDITOR.]

NOTICE.

The Committee of Publication thinks it proper to say that the Congress is to be held in no way responsible for the statements, reasonings, or opinions set forth in the various papers published in its Transactions.

ADDRESSES.

ADDRESS ON MEDICINE AND MEDICAL PROGRESS IN THE UNITED STATES.

BY

AUSTIN FLINT, M.D.,

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE, AND CLINICAL MEDICINE, IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

An important object of the Philosophy of History is the study of agencies concerned in originating and modifying past events. From this standpoint I propose to survey "Medicine and Medical Progress in the United States" during the past one hundred years. Whence were derived influences affecting the progress of Medicine in this Centennial period? I shall submit certain historical facts and reflections in answer to this inquiry. Another object of the Philosophy of History, of greater practical importance, is the study of agencies with reference to future events. Regarding Medicine in the latter aspect, the inquiry arises, by what influences is the progress of Medicine in our country to be promoted? This inquiry opens up a wide range of thought, to which some incidental reference is all that the limits of my discourse will permit.

Medicine, as I use the term in this discourse, distinguishes a province of knowledge and art from Surgery and Midwifery. In this restricted sense it denotes the province called in former times "the theory and practice of physic." I assume that medicine has steadily progressed in our country during the past one hundred years; the rapidity, at different periods, during this space of time, and the extent of progress, will naturally enter into reflections upon the influences affecting it. The scope of the term progress, as applied to Medicine, claims preliminary explanation. In what consists, and what are the criteria of, medical progress in this country, in past time? This question cannot be summarily answered; the answer will lead at once to the influences affecting the progress which has taken place, and to those which tend to its promotion now and hereafter.

The most striking evidence of progress is a great discovery, the practical benefits of which are immediate and palpable. Discoveries entitled to this distinction, within the past century, are vaccination, auscultation, and the separate functions of different components of the nervous system. This brief list cannot be much lengthened. Pre-eminently great discoveries in medicine are so distributed in respect of intervals, as to bear the impress of special gifts vouchsafed by Providence. We can boast of but one discovery which belongs in this category, the annihilation of pain by anæsthetic inhalations. It is true the brilliancy of this discovery is especially conspicuous in its applications to surgery; but the

benefits conferred on medicine are not vastly inferior, and would alone entitle it to rank with discoveries to be characterized as pre-eminently great.

Evidence of progress equally obvious, although less striking, is afforded by enlargement of the boundaries of knowledge in different directions. Under this head are embraced all facts relating to the nature of diseases, their anatomical characters, their causation, their discrimination from each other, their natural history, the principles of treatment, the relative value of remedial or curative agents, the introduction of new remedies or therapeutical methods and effective measures of prophylaxis. Not stopping to consider in these relations the history of Medicine in the United States during the past Centennial period, I pass to another aspect of progress.

The progress of Medicine in any country is shown by the prompt recognition of advancements in knowledge and improvements originating in other countries. After, for example, Harvey's great discovery, tardiness of its recognition in any country betokened lack of progress. So with regard to discoveries of every grade, and improvements great or small, it is proof of progress when they are promptly recognized in countries other than those in which they originated. Readiness in the importation of knowledge is thus a criterion, as it is, of course, a means of progress. I need not add that the rapid diffusion throughout a country of knowledge, either imported or of native growth, is both a criterion and a means of progress. Further, a spirit of progress is shown by the prompt recognition and diffusion, not alone of actual advancements in knowledge and real improvements, but of doctrines and novelties which fail to stand the test of time. Thus, in the eighteenth century, a spirit of progress must have been wanting wherever but little was known of the theories of Stahl, Hoffmann, and Boerhaave. This statement is not inconsistent with the belief that the prevalence of these theories impeded advancement in actual knowledge of medicine and real improvements in medical practice.

With these explanations of the term progress in Medicine, let us survey the medical history of the United States.

We celebrate in this anniversary the lapse of a hundred years of our existence as an independent people. A hundred years is but a small space in the life-history of a nation. We have passed through infancy; we are hardly beyond adolescence, and, as we hope and believe, senescence is far in the future. Our infantile and our adolescent condition are, of course, to be taken into account in our reflections upon the influences affecting the progress of Medicine.

When, in 1776, by a Cæsarean section, we were separated from the mother country, Medicine existed in a state ready for progressive development and growth. The number of educated and able physicians was by no means insignificant. Conspicuous among these were Rush, Morgan, Shippen, Thomas Bond, of Philadelphia; John and Samuel Bard, Peter Middleton, Richard Bailey, Jacob Ogden, Cadwallader Colden, of New York; Benjamin Gale, of Connecticut; Joseph Warren, William Aspinwall, and the centennarian Holyoke, of Massachusetts. At our nation's birth, the lives and labors of these men and their coadjutors had a potential influence in determining the commencing progress of Medicine. Medical education had an embryonic existence in two medical schools, one in Philadelphia and the other in New York, and there were germinations of medical literature.

In the history of American Medicine prior to the Revolution we find in operation a source of influence which has largely affected medical progress in this country during the last hundred years, namely, the recognition and adoption of advancements, real or apparent, in other countries. A striking instance in the colonial period was the introduction of the inoculation of smallpox by Zabdiel Boylston in 1771. Boylston inoculated his son about two months after the date of the inoculation, at the instance of Lady Mary Wortley Montague, of her daughter, and without knowledge of the latter fact. Boylston himself inoculated two hundred and forty-seven persons within a year after his first inoculation, whereas, in England, during that period, and prior to the inoculation of the daughters of the Princess Caroline, it had been practised in only twenty cases. Virulent as was the opposition on this side of the Atlantic, Boylston's life even being endangered, the practice in England was still more violently opposed. Its sinfulness was proclaimed from the pulpit, it being likened on one occasion to the smiting of Job with boils by Satan, "the delnded preacher," quoting from Boylston's biographer (Thacher), "wishing to have it understood that the Devil was the first inoculator, and that poor Job was his first patient."

The Revolutionary struggle, while it suspended teaching in medical schools, labors in literature, and studies requiring tranquil leisure, doubtless gave an impetus to medical as well as surgical progress. It enlarged opportunities for, and enforced closer attention to, the observation of certain diseases; it enhanced the urgency of prompt and successful methods of treatment; it opened up the subject of hospitals, and it stimulated to measures of prophylaxis. Herein is, in some degree, a compensation for the barbarism of war! It is not surprising, then, that, with the antecedent history of American Medicine, medical progress was renewed with much activity after the achievement of independence. As illustrations of this activity, after the war had ended (1783), and prior to the beginning of the 19th century, two rival medical schools in Philadelphia had gone into operation, coalesced, and been united with the University of Pennsylvania, the faculty then consisting of Rush, Kuhn, Wistar, Shippen, Benjamin Smith Barton, and James Hutchinson; the Philadelphia Dispensary for the relief of the sick poor, the first institution of its kind in the United States, had been established; the trustees of Columbia College in New York had organized a medical school, which, however, from local difficulties, had not accomplished much; a medical department of Harvard University had been instituted, with John Warren, Waterhouse, and Aaron Dexter as professors; medical societies had been incorporated in Massachusetts, New Jersey, and New Hampshire, and the publication of the "Medical Repository," a quarterly journal, which lived to the completion of twenty-three volumes, had been commenced. It is worthy of note that, prior to this century, Dr. Ezekiel Hersey, of Hingham, Massachusetts, had bequeathed a thonsand pounds, his widow the same sum, his brother, Dr. Abner Hersey, of Barnstable, and Dr. John Cuming, of Concord, each five hundred pounds, to be applied to the support of a Professor of Anatomy and Surgery in the Harvard Medical College. The sum of one thousand pounds toward the support of an additional professor had been bequeathed by William Erving, Esq., of Boston. It would have been pleasant to have cited these examples as precedents of many similar contributions for the promotion of medical education; but, it must be confessed, the subsequent history of Medicine in the United States furnishes little to boast of in this regard. It is, how-

ever, a question, the discussion of which would be here out of place, how far the interests of Medicine in this country would have been advanced by the endowment of professorships in medical colleges. As an illustration of interest in medical progress felt by persons not members of the profession, in 1798 Ward Nicholas Boylston secured to the Harvard School a fund yielding an annuity, for annual prizes for competitive dissertations on medical subjects, of one hundred and thirty-three dollars. These prizes are continued at the present day. The same public-spirited citizen of Boston founded the medical library which bears his name, and contributed in varions ways to the promotion of medical education. Another conspicuous illustration was the active co-operation of the great Franklin in founding and in the management of the Medical College of Philadelphia. Franklin was president of the board of trustees, and the meetings were held at his house until within a few months of his death.

During the period in our history of which I am now speaking, Cullen was the master-spirit in Medicine. Not content with being an expounder of the doctrines of Boerhaave, or a follower of his commentator Van Swieten, he promulgated a system of his own. He had the boldness to abandon giving lectures in the Latin language. His teachings, with those of his able colleagues Monro, Gregory, Black, Young, and Home, had made Edinburgh the centre of medical education. The College of Philadelphia, which in 1791 was merged in the Medical Department of the University of Pennsylvania, had been modelled after the school in Edinburgh, the latter having been modelled after the famous school of Leyden. All the professors of the Philadelphia College had graduated at Edinburgh. Hence, in this period of our history, the Cullenian system was adopted, although, as will presently be seen, its supremacy was not long maintained. It is evidence of activity at this period that an American edition of Cullen's work entitled "First Lines of the Practice of Physic" was published in 1781, his lectures on the Materia Medica having been published in Philadelphia in 1775.[1] Rush, in a letter to Cullen, written in 1783, said, in relation to the American edition of the "First Lines," that it "had a rapid sale and a general circulation throughout the United States. It was read with peculiar attention by the physicians and surgeons of our army, and in a few years regulated in many things the practice in our hospitals." He added: "Thus, sir, you see you have had a hand in the revolution, by contributing indirectly to save the lives of the officers and soldiers of the American army."

I have cited illustrations enough to show the activity of medical progress prior to the nineteenth century. The experience acquired in the war of the Revolution, the enthusiasm arising from the sense of national independence, the number of American physicians who had completed their medical education in European schools and imbibed the spirit of master minds in the profession, the pressing need of educated and skilful practitioners—these were potential influences affecting the progress of Medicine in the early days of the Republic.

Let me refer in this connection to the position held by the city in which we are assembled, in her relations to the progress of Medicine in the United States. At the time of the Revolution, Philadelphia was distinguished for her able and learned physicians and surgeons. They inau-

[1] For these and other facts relating to the history of this period, I am indebted to Carson's History of the Medical Department of the University of Pennsylvania.

gurated systematic medical instruction on this continent prior to the Revolutionary war, and again directly peace was declared. At the time to which our survey of the history of Medicine has extended, Philadelphia was the acknowledged seat of medical education. This pre-eminence she has held from that time to the present. In the number of medical men who have been educated at her schools; in the great preponderance of her medical literature, and in her large proportion of the distinguished representatives of the different departments of Medicine, she has had no compeer in the new world. To the influence of her example is to be attributed much of the activity of progress in other cities of the Union. If, in the future, she should cease to preserve the relative position which she now deservedly holds, it will be, in no small measure, from the spirit of honorable emulation awakened and sustained by her admirable example. In saying what I have said, I feel that I may assume to speak in behalf of the medical profession of the United States. It was most fitting that an International Medical Congress, in celebration of our centennial anniversary, should assemble in the city of Philadelphia.

We have now to inquire concerning influences affecting medical progress after the commencement of the nineteenth century. At the end of the first quarter of this century, there were at least twenty colleges in active operation, distributed among sixteen of the States of the Union, the number of students in the year 1825 exceeding two thousand. Of these twenty colleges, six may be distinguished as Metropolitan, being situated in Boston, New York, Baltimore, or Philadelphia. Let us do justice to the so-called Provincial schools as affecting medical progress. They furnished formal instruction to many who were unable to bear the expenses of long journeys and a residence in metropolitan towns. A considerable proportion of students then, as now, pursued their studies in part at institutions near at hand, and, in part, at schools in the cities just named. The provincial schools, each within a certain area, developed interest, inquiry, and study among members of the profession, thus raising the standard of medical acquirement. They awakened an ambition to become teachers by affording opportunity for the display of talent in that direction. If it be said that in the establishment of these schools the founders were not altogether disinterested, but may have been actuated by motives relating to personal distinction and success; this may be said with not less pertinency of metropolitan schools, and, moreover, such motives are not unworthy. If it be said that they have occasioned local jealousies and feuds; this is not less true of metropolitan schools. Thacher states with respect to the conferring of degrees upon the two first graduates of the Harvard Medical College, that, "from a spirit of envy and jealousy towards the professors, great opposition was made, and it was by the address and perseverance of John Warren that the object was finally accomplished." The success of medical schools in the city of New York was for several years retarded by local opposition; and the same difficulties were experienced in the early history of the schools in the "city of brotherly love." Not a few of the professors in the larger schools of our country first tested their powers, and acquired experience as teachers in the smaller schools. The latter have had not an inconsiderable share in promoting the progress of Medicine.

Within the first quarter of the present century, about twenty medical

journals were established. These contributed largely to the promotion and diffusion of medical knowledge. The subsequent multiplication of journals has not been proportionate to the increase and extension of our population, those now in existence not much exceeding twofold the number which had existed in 1825. Hitherto, as now, a considerable proportion have had a limited local circulation, having been issued generally in places where medical schools were established, and being in a certain sense the organs of the latter. These facts are not stated by way of disparagement. Of the great service rendered to medical progress by the larger and widely distributed journals, it is not necessary to speak; but, in justice to those comparatively small, and circulating within restricted limits, it should be said that they have in no small measure been serviceable. They have aided in diffusing medical intelligence. They have incited to reading, thought, and profitable discussion. They have increased the number of contributors to medical literature. It would be easy to cite numerous instances of valuable contributions which have appeared in journals relatively obscure.

The bibliography of the first quarter of the present century shows a fair list of original works, foremost in number and influence being the writings of Rush. Some of the works of this voluminous author, and other contributions to medical literature during this period, were republished abroad and translated into different languages. The profession of this country were by no means wholly dependent on foreign works. It would, however, have betokened a lack of the spirit of progress had an acquaintance with foreign authors been restricted by prejudice or indifference. It was far otherwise. English works were the authorities in Medicine, and many of those who could afford the time and expense, crossed the Atlantic (the voyages requiring at least two months) in order to finish their studies in Edinburgh or London, the schools in these cities at that time taking precedence of those on the continent of Europe. The reminiscences of the Revolutionary struggle, and a renewal of war with the mother country during this period, had no repressing influence on the attachment to the medical literature and the distinguished teachers of Great Britain. Is it unpatriotic to say this with gratification and pride? May we not claim in behalf of Medicine that it tends to raise its followers above political contentions! May I not refer to our late domestic strife as affording illustrations of a brotherhood which the legitimate objects of Medicine render impregnable!

As a source of influence affecting the progress of Medicine, the formation of medical societies in the early, and still more in the latter, part of the present century is to be mentioned. Without going into historical details, suffice it to say, that thereby the advancement and diffusion of knowledge have been greatly promoted. Moreover, to voluntary associations is due, in a great measure, the character of the profession as regards medical ethics and its position in relation to illegitimate systems of practice. I must be content with simply referring, in this connection, to one of the most important of the agencies concerned in medical progress.

In pathology and therapeutics during the early part of the present century, the influence of Cullen, surviving his death, was still great. Rush, however, a pupil and a fervent admirer of Cullen, was too bold and independent a thinker to be satisfied with being an expounder of his teacher's doctrines. In those days an object of medical philosophy was

to reach a theory which should reduce to a simple system the practice of medicine—an object which, were it attainable, would obviate many of the difficulties in the way of diagnosis, embarrassing the practitioner of the present day. Rush was the author of a theory, the unity of disease. According to this theory all morbid phenomena are the varied manifestations of a single entity. This is not the time nor place to enter into any discussion of the merits of medical theories, or to consider their practical effects. Whatever may be thought of the "theory and practice of physic" as taught by Rush, he influenced largely pathological views and therapeutics during his lifetime, and the influence of his writings continued after his death. The system of Brown, the opponent of Cullen, had its advocates in this country—a system leading to rules of practice directly in conflict with those inculcated by Cullen and Rush. Even the extravagances of Darwin's Zoonomia, which was republished in New York and Philadelphia in the latter part of the eighteenth century, with an introductory address and an appendix by Charles Caldwell, were not without influence. Toward the close of the first quarter of the present century (1823) the "Study of Medicine," by John Mason Good, was republished in Boston, a work inaugurating the "physiological system" in nosology and practice. It is evidence of a true spirit of progress that, of the different systems, none had exclusive sway, and that, although there were enthusiastic partisans of each, many, if not the majority of, thinking minds were guided by a rational eclecticism, selecting from any whatever commended itself to reason and experience. With regard to this point I quote from the worthy historian of "Medicine in America," Thacher, the following, written in 1828: "We recognize in our institutions no uniform theoretical system as the rule of practice. Medical history affords abundant evidence of the instability of human systems. Every age has teemed with theories or visionary hypotheses fleeting as the wind, scarcely surviving their authors, but yielding to others as transient and unsubstantial as themselves. The medical authorities most respected are Cullen, Rush, and Good. These, modified and improved according to the judgment and views of the respective professors, are adopted and taught in the various American universities."

The introduction of vaccination in the beginning of this century was a striking instance of the prompt recognition and adoption of a great discovery. Jenner's "Inquiry into the Causes and Effects of the Variolæ Vaccinæ" was published in London in 1799. In the following year Benjamin Waterhouse vaccinated four of his children with virus received from Jenner, and tested their insusceptibility to smallpox by exposing them to infection in a hospital for the treatment of patients with the disease. In 1801, Valentine Seaman commenced vaccination in New York. Its speedy employment throughout the United States was unattended by the violent opposition which characterized its early history in the country honored by this greatest of all discoveries, as measured by its influence on the physical welfare of mankind.

In 1817, an important event denoting progress was the project for the formation of a National Pharmacopœia. This project originated with Lyman Spalding, and the initiatory steps were taken by the New York County Medical Society. In 1820, a convention of delegates from the different medical colleges and societies throughout the Union assembled at Washington and adopted an American Pharmacopœia, which, with decennial revisions, has been continued up to this date.

The second quarter of the present century is an eventful period in the history of Medicine. The great American discovery of the annihilation of pain by anæsthetic inhalations was made in this period. It is significant of a cosmopolitan spirit pervading the medical profession throughout the civilized world, that this discovery was at once recognized and adopted in other countries. The first application to capital operations in surgery was in Boston, in September, 1846; and in the following January the brilliant success of this application was demonstrated in the hospitals of London and Paris. Directly following the application to surgery, anæsthetic inhalations entered into the treatment of diseases both here and abroad.

Surveying the more memorable of the events relating to the medical knowledge of this period, it began with the advancement of morbid anatomy to the rank of a distinct department of medical study. This was the result of the labor of Bichat, which gave birth to General Anatomy. That great work, the "*Anatomie Générale*" of Bichat, translated by George Hayward, was published in Boston in 1822. Bayle and Hollard's Manual of General Anatomy was translated by Gross in 1828, and Béclard's Elements of General Anatomy, which appeared in 1823, was translated by Joseph Togno, and published in Philadelphia in 1830. The Profession of this country were prepared by these works, together with the older works of Baillie, Meckel, Portal, Laennec, and others, for the grand development of this study by Cruveilhier, Andral, Lobstein, in France; by Mueller, Gluge, Otto, Henle, Vogel, Hasse, Rokitansky, in Germany; and by Carswell, Craigie, Hodgkin, and Hope, in Great Britain. With the writings of these distinguished authors the Profession of this country became immediately conversant. Some of the French and German works were translated, and all were brought to the notice of medical readers by means of analytical reviews. The spirit of progress was shown by the efforts to keep pace with the advancement in other countries. To compete with these in the bibliography of this study was not to have been expected; yet in 1829 appeared "A Treatise on Pathological Anatomy," by Horner, in two volumes; and in 1839 an elaborate work by the honored President of this International Congress, then a professor in the State which gave to the profession McDowell. Horner and Gross were thus pioneer authors in this branch of American medical literature. It is noteworthy that, for several years prior to the publication of the work by Gross, he had held a chair of pathological anatomy in the Cincinnati Medical College. I am fully warranted in saying that this field of observation was diligently cultivated by not a few, and that there was a general appreciation of its importance in relation to the knowledge of diseases. To the study of Pathological Anatomy during nearly all the period to which our attention is now directed, and up to the present moment, have been devoted the labors of one who, had he not been, unfortunately (I would almost say, with the utmost respect, blamably), satisfied with the gratification pertaining to his attainments, together with his usefulness as a professor, and his invaluable services as curator of one of the richest of the museums in this country, if not in the world, his name would have become so identified with the study in the medical literature of every country that it would have been superfluous to refer in this manner to J. B. S. Jackson.

The discovery of auscultation can hardly be said to have had much efficient influence on the progress of Medicine prior to the second quarter

of the present century. It is true, Laennec's great work was published in 1819, and the translation by Forbes appeared in London in 1821; but the discovery met with distrust, and was disparaged by some authoritative authors. Forbes's translation was republished in this country in 1830, and from this date the great value of auscultation began to be recognized. Soon after this date James Jackson, Jr., opened up the study of the abnormal modifications of expiratory sounds, which Laennec had, in a great measure, overlooked. In 1835 Gerhard published a treatise on the diagnosis of thoracic diseases to "supply the wants of his classes and of others who felt an interest in the subject." In 1836 the Massachusetts Medical Society published dissertations, by Oliver Wendell Holmes, Robert W. Haxall, and Luther V. Bell, submitted in competition for a Boylston prize, which was adjudged to Holmes. As early as in 1832 James Jackson, in his visits at the Massachusetts General Hospital, always carried a stethoscope, the counterpart of that which Laennec was accustomed to make with his own hands; and the daily record dictated at the bedside of each patient embraced signs obtained by percussion and auscultation. It was not long before physical exploration by these methods entered more or less into clinical and didactic teaching in most of our medical colleges, and thence speedily found its way into private as well as public practice. The Profession of this country were not tardy in accepting the fruits of Laennec's discovery, and this branch of practical medicine has ever since had with us not a few zealous votaries. Our medical literature, during the past forty years, contains a good proportion of contributions relating to it.

The physical diagnosis of diseases of the heart, which at the present time has reached such perfection, may be said to have had its point of departure in the works of Bouillaud and Hope. Hope's treatise, issued in London in 1832, was republished, with notes by the late Dr. C. W. Pennock, in Philadelphia in 1842. In the interim Dr. Pennock and Prof. E. M. Moore, of Rochester, N. Y. (1839), had devised and carried out a series of accurate experiments to elucidate the mechanism of the heart sounds. At the end of the second quarter of the present century, the progress in this province of medicine had been made familiar to American medical readers by the republished works of Andry, Raciborski, Barth and Roger, Aran, Stokes, Latham, Walshe, Blakiston, Watson, and by the writings of Gerhard, Bowditch, and Swett in our own country.

A memorable event in the medical history of this period was the publication, in 1827, by Richard Bright, of his "Reports of Medical Cases." A full analysis of this work appeared in the February number of the first volume of the "American Journal of the Medical Sciences," in 1828. The editor concluded the article with these words: "As Dr. Bright's volume is so costly as to preclude its circulation in this country, and as its contents are highly interesting, we have been induced to extend our notice beyond the usual limits, and have placed in our periscope some of the most interesting cases." I make this reference to show how quickly important contributions to our knowledge abroad were brought to the notice of medical readers on this side of the Atlantic. The name *Morbus Brightii* had not as yet been applied to affections, the anatomical characters of which Bright was the first to describe. Naturally, the morbid anatomy of these affections for some time engrossed attention; the fruits of their clinical study could not be gathered at once. It was not until the publication of Christison's work, in 1839, that the profession in Great Britain and this country began to grasp the scope of

their pathological relations. Bright himself could hardly have dreamed of the extent of the new field in pathology which his researches opened up. Our present knowledge of uræmic conditions in etiology and symptomatology, acquired chiefly during the last quarter of the present century, he could not have anticipated. I think it not too much to say that the progressive developments in this field of pathology have been as fully appreciated and their influence on the practice of medicine has been as marked in this as in any country.

The quotation just made from the "American Journal of the Medical Sciences" leads me, in this connection, to refer to analytical reviews and bibliographical notices as affecting medical progress. This journal, succeeding the "Philadelphia Journal of the Medical and Physical Sciences," in fact a continuation of the latter, dates from the year 1827. In the advertisement accompanying the first volume it was said: "Arrangements have been made to import regularly from London and Paris every new medical work, and to obtain in exchange almost every medical journal published in Europe. These will be placed in competent hands for analysis or review, and whatever is valuable in their contents shall be laid before our readers as early as possible." Writing, as I do, after having examined the volumes issued during the second quarter of the present century, I am impressed with the fidelity with which this promise was fulfilled. They contain reviews or notices of the important publications in England, France, Germany, and other countries during that period. This journal, continued up to the present time, under the same title, issued by the several successors of the first publishers, Lea & Carey, for more than forty years under the editorship of Isaac Hays (who, although a veteran in journalism, is not yet entitled to be called venerable), has had a powerful influence on the progress of Medicine in this country. This influence has been exerted not less by its original communications than by its reviews, notices, and general intelligence. Without any disparagement of the numerous able and useful periodicals during the last half century, may we not, with a feeling of pride, refer especially to a journal which, with such a history, is now the oldest representative of medical periodical literature, and which has probably a circulation larger than that of any other in Europe or America?[1]

The physiological discoveries of Magendie, Charles Bell, and Marshall Hall, relating to the nervous system, forerunners of a further unfolding of the functions of this system within late years by Bernard, Brown-Séquard, and others, had a considerable influence on pathology and practice; an influence which, by means of republications, reviews, and controversial articles, was perhaps felt as speedily here as abroad. But a memorable event in physiology, having direct practical bearings, was of American origin, namely, the observations and experiments of Beaumont in the case of Alexis St. Martin, published in 1833. Beaumont's prolonged, patient, careful, conscientious researches, demonstrating more completely than had yet been done the agency in digestion of the gastric juice, furnished important facts in relation to its quantity, its composition, the circumstances affecting its secretion, together with the relative digestibility of different articles of food, and the influence upon digestion of local and general morbid conditions. These facts have, in the main, been corroborated by experimental physiologists who have since studied

[1] The American Journal of the Medical Sciences is the oldest of living journals, considering it as a continuation of the Journal of the Medical and Physical Sciences.

the functions of the stomach by means of artificial gastric fistulæ in inferior animals. Looking at the fruits of his labors as affecting the progress of medicine, may we not claim for them sufficient value to entitle the name of Beaumont to be mentioned in connection with the names of Magendie, Bell, and Hall?

The writings of Broussais are to be reckoned among the memorable events of the period under survey. The "History of Chronic Phlegmasiæ" was translated by Isaac Hays and R. Eglesfeld Griffith in 1831; in the same year his "Treatise on Physiology applied to Pathology" was translated by John Bell and La Roche, and in 1832 his work entitled "Propositions Embodying Principles of Physiological Medicine" was translated by Hays and Griffith. By these publications the profession in this country were made acquainted with the so-called new physiological doctrine more commonly known as Broussaism. For a time it had not a few ardent supporters, prominent among whom was the late Professor Samuel Jackson, whose work, entitled "Principles of Medicine," was based upon it. The circulation of this work was arrested by the author, as was understood, because it became inconsistent with his more matured views, an act which reflected honor upon his character as an honest inquirer after truth. Like the systems of Rush, Brown, and Cullen, Broussaism had its day; but, unlike the preceding systems, this has had no successor. With the fall of Broussaism the race of *isms* became extinct; theoretical dogmas as the basis of different schools or sects have been relinquished to the illegitimate *pathys*.

Broussais, however, was not the sole last survivor of the race. Coeval with this doctrine was one of American birth, namely, the doctrine of Cooke. John Esten Cooke, a man of much ability and of sterling moral worth, at that time Professor of the Theory and Practice of Medicine in the worthily distinguished Transylvania University, in 1831 published at Lexington "A Treatise on Pathology and Therapeutics." After commenting on the extreme proneness of medical philosophers to frame hypotheses instead of following the true spirit of inductive logic, he enunciated the doctrine that hepatic congestion is the *fons et origo* of most of the phenomena of disease. This doctrine was not entirely new, but it was carried by Cooke to the extreme point of culmination. Its practical effect on therapeutics was an excessive use of purgatives, and especially calomel in large doses. In those days of hypercatharsis, patients were purged by the followers of this system as patients had never been purged before. Cooke was afterward Professor of Practice in the Medical School at Louisville, and for a long time a dose of calomel which he had prescribed was preserved as a curious specimen in the museum of that school. With the audacious extravagance which characterizes American humor, it is related of a Kentucky yeoman that, finding in one of his fields crude mercury in considerable quantity, visions of wealth from a mine of quicksilver loomed up in his imagination; but they were dispelled when it was ascertained that the spot had been a burial ground for the remains of patients treated in accordance with this doctrine!

An influence which contributed to prevent the formation of new systems of medicine, and to promote in not a small degree, true medical progress, belongs to the works of Louis. Louis's "Researches on Phthisis," translated by Cowen, revised and altered by Bowditch, his "Researches on the Typhoid Affection," translated by Bowditch, and his "Researches on the Effect of Bloodletting in some Inflammatory Diseases," translated by Putnam, with a preface and appendix by James Jackson, were

published in this country in 1836. His "Researches on Yellow Fever," translated from the manuscript by Shattuck, appeared in 1839. I need not enter into an exposition of the method of study which Louis exemplified in these works. It would be out of place, even if time permitted, to discuss here the merits of this method. Of its influence, suffice it to say that it has led to a large proportion of the actual knowledge of the clinical history of diseases, of their anatomical characteristics, of the diagnostic value of symptomatic phenomena and of therapeutical agencies, which has been acquired within the past forty years. Of the permanency of acquisitions in knowledge to which it has already led, let this statement suffice; the works of Louis, within the limits of the means of observation available in his time, are as valuable to-day as at the date of their appearance. The method of study inaugurated by him was a new departure of the Philosophy of Medicine, offering now, and in all time, rich returns for honest work.

The study of medicine in the direction given to it by the labors of Louis, led to an appreciation of the importance of knowing the natural history of diseases. Jacob Bigelow struck a key-note in his discourse on "Self-limited Diseases" in 1835. From that time our teachers and writers have been alive to the truth that knowledge of the intrinsic tendencies of diseases must underlie actual progress in therapeutics. The true spirit of medical philosophy, after its emancipation from the thraldom of theoretical systems, speedily found expression in the works of Stillé, Bartlett, Ware, Holmes, and others. The influence was soon felt in medical practice. Progressively, in this country, practitioners became more reserved in the use of heroic measures of treatment, and polypharmacy fell into disrepute; they became less ambitious to be the masters, and more content to remain the servants of nature; efforts were made to bring experience to the test of the numerical method of investigation, and "expectation," using this term in its true sense, took its proper place in clinical medicine. Is it presumptuous to affirm that these criteria of veritable progress have been not less, and perhaps, in some regards even more marked in the medical practice of American physicians than of those in the older countries, by whose writings and oral teachings we have largely profited?

Warned by the length already of this discourse, I must not linger with other topics relating to the history of the second quarter of the present century. There are two events of importance, belonging to this period, to be added to those already noticed, namely, the publication of the United States Dispensatory and the organization of the American Medical Association. The first edition of the Dispensatory by Wood and Bache was published in 1833. With the additions and improvements called for in the successive thirteen editions, this work has met fully the wants of the practitioner, holding its place still, without a competitor, and, to say the least, comparing favorably with similar publications in other countries. The American Medical Association was instituted in 1847, by the Profession, "for the protection of their interests, for the maintenance of their honor and respectability, for the advancement of their knowledge and the extension of their usefulness."[1] Since its organization annual meetings have been held, excepting a portion of the period during which intercourse of the Profession of the North and the

[1] Quoted from the resolution adopted by the Convention which preceded the first meeting of the Association.

South was suspended by civil war. At these meetings representative members of the profession in all parts of the country have been brought together under circumstances conducive to fraternal union and good fellowship; and the twenty-six volumes of "Transactions" contain much that is valuable, more especially in relation to climatology, and the diseases prevalent in different parts of the United States. The Association has encouraged original papers by prizes, and has kept the Profession informed of important contributions to knowledge by reports on Medical Science and Literature, and on the Progress of Medicine, Surgery, and Midwifery. In these different ways its influence has been not inconsiderable.

The literature of any province of knowledge gives the truest expression of progress, while it does most toward promoting it. In this period, the increase of publications was proportionate to the growth of our nation in population and material interests. I shall enumerate some of the valuable contributions to practical medicine, without attempting to give a full list of them. My distinguished friend who will address the Congress on the subject of American Medical Literature will supply deficiencies here and elsewhere.

The "Practical Esssay on Typhous Fever" by Nathan Smith, although printed in 1824, may be reckoned as entering into the literature of this period. One of our most accomplished writers (Bartlett) in his work on the Fevers of the United States, published in 1842, says of this "modest unpretending essay:" "To an American practitioner it is worth infinitely more than all the modern English treatises put together." The attainments and skill of that great man, united with perfect integrity and simplicity of character, excite our admiration; nor can we less admire the energy and pluck which led him to establish the medical school of Dartmouth College, himself the sole professor for ten years, a faculty of one, but that one Nathan Smith, prominent among the medical heroes of the early age of our republic.

The progress of knowledge of the essential fevers, within this period, was in no small measure affected by contributions to American medical literature. Gerhard, Pennock, in 1836, and Shattuck, in 1839, were the first to contribute ample clinical observations, showing the essential points of distinction between typhus and typhoid fever. To these observers belongs the credit of the doctrine of the non-identity of these fevers, a doctrine which, after twenty years of hesitation and discussion, was generally recognized as sufficiently established. James Jackson's Report, in 1838, and Enoch Hale's paper, in 1839, embodied the results of the application of the method of study inaugurated by Louis to the common continued (typhoid) fever of New England. The treatise on the Fevers of the United States by Elisha Bartlett, published in 1842, the fourth edition revised after the author's death by Alonzo Clark, has been, almost up to the present time, a standard work, and is too well known to need any commendation. Meredith Clymer, in an article on typhoid fever, published in 1846, was the first to describe in this country the disease now known as relapsing fever. It may, perhaps, be assumed that the communicability of typhoid fever was first demonstratively shown by the circumstances attending an outbreak of the disease in a small hamlet in Western New York, in 1843.[1]

[1] Account of an epidemic fever which occurred at North Boston, Erie Co., N. Y., in October and November, 1843. American Journal of the Med. Sciences, July, 1845.

Important contributions relating to the differential characters of remittent fever and its clinical history were made by Stewardson, in 1841 and 1842; by Swett, in 1845; by Anderson, Frick, Stillé, and Boling, in 1846. Our present knowledge of this disease rests mainly on the facts contained in these contributions.

The doctrine of the combination of different fevers, or the "blending of types," was taught by Dickson and Drake, in contradiction of the theory of Hunter, which denied that the special causes of two or more diseases can act conjointly in the organism. The doctrine is now sufficiently established by clinical proof. Drake, in 1832, contributed a series of papers in advocacy of the animalcular hypothesis of the origin and diffusion of epidemic cholera, and subsequently, in his great work, he argued at length, and cogently, for this hypothesis as applied to the etiology of other diseases. And in this connection the remarkable work of Mitchell on the "Cryptogamous Origin of Malarious and Epidemic Fevers" may be referred to. This work was published in 1849. If, as is perhaps more than probable, the truth of the "germ theory," as it is now termed, be hereafter confirmed by direct observation, the writings of Mitchell and Drake on this subject will be cited as evidence of an insight into the mysteries of etiology beyond that of their contemporaries; and at the psesent moment, when this theory is the subject of so much interest, these writings claim careful study.

In referring to Drake, I cannot forbear a passing tribute of admiration of the talents and labors of that truly great man. As an eloquent expounder of medicine he was without a superior; and when we look at the work which he performed, as a writer, a medical teacher, and in travelling over large sections of our country, gathering from personal inquiries and observations materials for his treatise on the "Principal Diseases of the Interior Valley of North America," which he did not live to complete, we must consider his name as worthy to be enrolled in the list of our medical heroes.

The treatment of the periodical fevers with large doses of quinia, together with the discontinuance of the so-called preparatory treatment; the extent to which this drug may be given without risk of harm; the entire safety of its use in the state of pyrexia; and the advantage of arresting the paroxysms as speedily as practicable—points at that time in opposition to the prevalent practice—were set forth in this country as early as 1841.[1] It may be added that the views which have since prevailed in reference to these points were adopted earlier, and diffused more quickly with us than in other countries.

The literature of this period embraces many contributions relating to yellow fever. Prominent among the contributors are the names of Barton, Barrington, Cartwright, Dickson, Nott, Simons, C. H. Stone, Ashbell Smith, and Fenner. Our medical literature from the earliest period of our history has abounded in writings on this subject, to which justice has been done in that marvel of laborious erudition, the Treatise on Yellow Fever, by La Roche, published in 1855. The contributions by the authors just named, and others, led to the present prevailing belief in the non-communicability of the disease, but the portability of its special cause, and in the injudiciousness of perturbatory measures of treatment.

Of contributions other than those relating to the essential fevers, and

[1] *Vide* article in the American Journal of Medical Sciences, No. for October, 1841.

in addition to those referred to in other connections, I shall mention several, by no means undertaking to enumerate all, or even the greater part, of those which promoted progress by extending, more or less, the boundaries of knowledge.

John Ware, in an analysis of his recorded experience published in 1831, brought to bear the numerical method upon the use of opium in the treatment of delirium tremens. The results of the analysis have ever since been a basis of practice in that disease. The same writer in a series of articles on croup, published in the latter part of this period, delineated clearly the different affections then embraced under that name. The distinctions derived from his recorded experience and founded in nature, are as valid to-day as at the date of their publication.

John B. Beck's treatise on infant therapeutics in 1849, had much influence in restraining the over-use of potential measures in the treatment of diseases in infantile life. The article by Cammann and Clark on auscultatory percussion, published in 1840, introduced a new method in physical exploration, and gave the results of its employment in obtaining accurate measurements of internal organs. The treatise by Amariah Brigham on "The Influence of Mental Cultivation on Health," published in 1832, and the "Inquiry concerning the Diseases and Functions of the Brain, Spinal Cord, and Nerves," published in 1840, contained original views important in their practical applications. Horace Green's treatise on "Diseases of the Air Passages," published in 1846, originated the practice of making topical applications within the larynx, the feasibility of which was accepted after considerable distrust and acrimonious discussion. In 1841 Alonzo Clark began to treat acute peritonitis with large doses of opium, excluding calomel and venesection. He carried the use of opium further than had previously been done, and ascertained that the disease in some cases causes a marvellous tolerance of this remedy. The treatment exclusively or chiefly by opium has been generally adopted in this country, and may properly be called the American method. Moreover, the success of the use of opium freely in peritonitis, has led to the useful employment of this remedy in other affections. Bowditch's first employment of suction for the withdrawal of liquid from the pleural cavity, through a small canula, was a few weeks after the end of this period; but he then carried into effect a procedure which he had previously maturely considered and resolved upon. I may, therefore, in this connection, refer to an improvement in the practice of medicine, the merits of which it were needless at this day to discuss. The use of the term *aspiration*, in place of the homely word *suction*, and the invention of more complicated instruments, have recently given to the procedure a new and more attractive aspect. The successful practical application of the method, however, belongs to the history of American medicine; and, taking into view the wide range of the application, it is certainly worthy of being reckoned among the important events affecting medical progress within the past century.

These contributions, cited from personal recollection, without searching medical annals in order to extend the list, suffice to show that during this eventful period, the field of practical medicine in this country was not without efficient workers, and not wholly unproductive. Directing attention to another aspect of medical literature, the evidence and the means of progress are shown by the number of works relating to the Principles and Practice of Medicine. Original works in this department of literature began to appear prior to the second quarter of the present

century; but the number within this period was considerable, namely, the works of Dewees, Eberle, Dunglison, Cooke, Fort, Gallup, Hosack, Chapman, Paine, Dickson, Stillé, and Wood. A considerable number of republished works, generally with notes or additions by American editors, were added to those of native production. In this list are the works of Marshall Hall, revised and much enlarged by Jacob Bigelow and Oliver Wendell Holmes, Craigie, Billings, Elliotson, with notes by Stewardson; Gregory, with notes by Peixotto, Alison, Williams, and Latham; Graves's System of Clinical Medicine, with additional lectures by Gerhard, and Stokes's lectures with an equal number added by Bell; Andral's Clinique Médicale, translated by Spillan; Chomel's Pathologie Générale, translated by Oliver and Morland, and the lectures by Watson. In addition to works of this character were several on a larger scale designed for reference in regard especially to the practice of medicine, namely, the London Cyclopædia of Practical Medicine, edited with large additions by Dunglison; Copland's Medical Dictionary, with copious notes by Lee; the Library of Practical Medicine by Tweedie, with American notes and additions by Gerhard. To this class of works belongs the American Cyclopædia, edited by Hays. When to these productions, native and foreign, we add the original treatises by Dewees, Eberle, Condie, and Stewart on the diseases of children; not a few works, original and imported, treating of particular classes of diseases; the works on materia medica by Barton, Bigelow, Coxe, Chapman, Eberle, Dunglison, Griffith, Carson, Paine, Ellis, Beck, Bell, Harrison (all native productions), and the medical dictionary, by Dunglison, have we not, in this point of view, evidence of an activity in the means of progress creditable to a nation under the age of fourscore years? Was not the growth of medical literature, in this aspect, proportionate, to say the least, to the increase of population, the extent of territory populated, and the advancement in other provinces of practical knowledge?

Survey for an instant this period from one other standpoint, namely, the number and character of prominent members of the medical profession. We must recognize in the personal influence exerted by individuals in their respective spheres as teachers, practitioners, and members of society, one of the most potent of the agencies concerned in progress. Some of those who, regarded from this standpoint, have a record most honorable to themselves, are still with us—may they live long to receive the honor which is their due! On the list of those who have departed for another life are such names as James Jackson, Samuel Jackson, Samuel Jackson of Northumberland, Chapman, Mitchell, Hosack, Ware, Gerhard, the two Becks, McNaughton, Pennock, Revere, Drake, Joseph M. Smith, Francis, Parrish, the elder Shattuck, Dunglison, Dickson, Fenner, Stearns, Bartlett, Moreton Stillé, Caldwell, LaRoche, Lee, Swett, Twitchell, Tully, Mussey; and to these, and such as these, might be added the names of a host of practitioners who, without engaging in the labors of literature, or in medical schools, exerted within greater or lesser spheres, an influence promoting the diffusion of knowledge and ennobling the character of the physician.

Having reached in our survey the third quarter of the present century, I hasten to say that the concluding part of my address will be brief. I shall not enter into historical details for reasons which are obvious, in addition to the desire not to presume too much upon your patience. The professional lives of a considerable proportion of those whom I address

embrace the last twenty-five years, and everything of importance pertaining to the history of this period is familiar to them. Moreover, to particularize events, to notice contributions to medical literature, and to refer to individual members of the profession, would involve questions of delicacy which I prefer to avoid. I shall therefore limit myself to a few remarks on topics suggested by the inquiry, what are some of the characteristics of medical progress in the United States within the last quarter of a century and at the present time?

The predominant and most distinctive characteristics of progress in the medical science of this period, are derived from the developments in histology. Pathological histology followed the acquisition of a new territory in anatomy by Schwann in 1839, as the morbid anatomy of the tissues had followed the *Anatomie Générale* of Bichat; and the developments by means of the microscope in the study of disease are to be dated chiefly after the middle of the present century. Prior to this, however, microscopy had enlisted the interest of medical teachers and students in this country, as well as in Europe; and as early as 1851, a prize was awarded to Burnett (whose untimely death was a loss to science), by the American Medical Association, for an essay on "The Cell; its Physiology, Pathology, and Philosophy," embracing deductions from elaborate original investigations. Histology entered at once into the formal instruction of many, if not most, of our medical schools. Our pilgrim sons who previously had paid homage at Paris, Edinburgh, Dublin, and London, for the past quarter of a century have gathered in larger numbers at Vienna and Berlin. Histological researches having been prosecuted with most zeal by our Austrian and Prussian brethren, German medical literature has thereby acquired a prominence and an influence which might be cited as a characteristic of Medicine at the present time. I need hardly say that it would not be fitting on this occasion to inquire into the actual increase of our knowledge to be ascribed to the progress of histology. That a vast and fruitful domain in physiology and pathology has been brought under cultivation, and that it has already yielded rich harvests, cannot be doubted. Herein will the history of Medicine in our day be ever memorable. And the future is full of promise when obstructions from doctrines connected with bioplasm, cyto-blastema, autogenesis, and the so-called cellular pathology shall have disappeared. With improved methods and increased power of microscopical investigation, it may not be long before the *germs* (using this word in either a literal or a figurative sense) of infectious and contagious diseases will be brought within the scope of ocular demonstration. When this is accomplished, it requires no prophetic sagacity to foresee that the influence on the progress of pathology, therapeutics and prophylaxis must be immense. Perhaps in the developments of the future, the labors of our zealous workers will bear an honorable part. I will venture to add that we are not to expect from histology a royal road through pathological mysteries; but, profiting by past experience, and avoiding doctrines based largely on hypotheses, our researches in this direction should go hand in hand with the tedious, but, if properly conducted, safe studies in clinical medicine.

I have alluded to pilgrimages to other countries. The desire to profit by the distinguished schools abroad has always been an American characteristic. In the first half century of our national existence, the schools in Great Britain were chiefly resorted to; in the third quarter of the century, those of France had the preference, and in the last quarter the

2

German schools. Some members of the Profession look with disfavor on this yearning for foreign instruction. It is thought to be antagonistic to a proper sense of a national independence, implying a sort of vassalage unfavorable to original developments. I do not share in these views. For us, in our adolescent age, to regard with a certain degree of deference the institutions of older countries, is not a confession of dependence, but a becoming modesty. It is true that opinions which have travelled across the Atlantic acquire in the estimation of many an exaggerated importance; the weight of far distant authority is apt to be over-estimated. This is, in a measure, counteracted by judgments formed after personal inspection. A discriminating mind judges fairly from intercourse with distinguished teachers and writers of their claims as authorities. In this point of view our sojourners abroad benefit, not only themselves, but their brethren at home. In some instances, it must be admitted, personal admiration or attachment leads to a discipleship which is exceedingly unfavorable to the progress of the disciples; yet these render service by diffusing the opinions of their masters among those who, uninfluenced by partisan zeal, consider and judge without prejudice. That our independence in thought and judgment is not compromised, is shown by what I believe may be stated as a fact, namely, no one who has returned from abroad and remained a mere satellite of a foreign luminary, has ever attained to any great distinction in the minds of his countrymen.

A characteristic of the past quarter of a century, and of the present time, relates to the increase of American medical literature. Native productions have been and are steadily increasing in number, and this not to the exclusion of, if, indeed, there have been any decrease in, the republication of foreign works. In order to appreciate the significance of this increase, as showing the progress of native literature, we must consider that American productions are in immediate competition with English works, the merits of which have been established, and for the republication of which the authors can claim no royalty. Much has been said of the injustice done to American authors by the want of an international copyright law. Without entering into any discussion of this topic, I will simply say that such a law is called for, not so much for the encouragement of our own literature, as in behalf of the just claims of foreign authors. The medical profession of this country have given ample evidence of a disposition to receive with discriminating favor native productions. I presume I am not in error in saying that our medical publishers are always ready to print any work which, from its intrinsic merits, may offer a fair promise of success. This is evidence of a demand for native works, inasmuch as it would imply a marvellous disinterestedness to suppose that publishers are actuated solely by a desire to promote a national literature. It is noteworthy that not long after French authors were held in special favor, the proportion of medical readers who were able to study the works of these authors in the language in which they were written, became so large as to render translations unprofitable to publishers; and it is probable that ere long this will be found to be the case in regard to publications in the German language. There will then be no occasion for a remark which I have heard imputed to a medical teacher in this country, that to know the German tongue is as essential for the student of medicine as a knowledge of anatomy!

I cannot forego a few words respecting the disposition of our English-speaking foreign brethren toward American medical literature. Many years ago an English reviewer and humorist, in a moment of irritation

from circumstances of a personal nature which rendered it perfectly natural, exclaimed, "Who reads an American book?" This has been over and over again quoted as a fair expression of the estimate in England of our bibliography. It should never be quoted except to add that its author was more unjust to his own countrymen than to us. All who are familiar with the medical periodical literature of Great Britain must have been impressed with the great candor and consideration generally shown in reviews and notices of American works. Not unfrequently these have received far more approbation abroad than at home. This is certainly a fitting occasion to declare that there is no ground to impute a prejudice, either in Great Britain or any other country, against our national literature.

That our works and periodical literature have in general a practical character is readily accounted for by our youth as a nation, and the rapid extension of population over a vast continent. With increase of years, and the altered circumstances incident thereto, our future in medical literature, it may safely be predicted, will show a wider scope. Thus far in our progress, the pressing claim upon our writers has been the wants of our widely separated brethren as regards qualification for the active duties of the practitioner.

The statement just made suggests the leading characteristic of our medical schools, namely, practical instruction. I shall not encroach upon the ground of the distinguished physician who is to address us on the subject of American medical education. He may, perhaps, point out defects in our educational institutions. That there are defects, is not to be denied. But, that we may not do injustice to our predecessors and our contemporaries, let it be considered how peculiar is the situation of the profession of this country in this regard. The whole responsibility for medical education, inclusive of the means for its promotion, rests, for the most part, with the Profession. Medical schools are without the jurisdiction of the general government, and our numerous States can only control, of course, those within their respective borders. Hence, uniformity throughout the country in legislating in behalf of medical education is impracticable. Legislative provisions for the increase and diffusion of medical knowledge are apt to be regarded in the light of appropriations for the benefit of a particular class of citizens. A diploma or a license to practise medicine from some legally authorized body is easily obtained, and the law practically places no obstacle in the way of practising without either. Now, in view of these facts, which are, of course, familiar to all of us, how are we to explain the annual gatherings of medical students and practitioners in large numbers in Philadelphia, New York, and other cities, many coming from distant parts of the Union, incurring expenses which often involve much exertion and self-denial? What other explanation is there than, *first*, that certain of our medical schools afford large opportunities in the way of practical instruction; and, *second*, that there is a wide-spread yearning for these opportunities simply on account of their intrinsic worth? Have we not here the evidence of a spirit of progress in both teachers and pupils, which is creditable to the past and present, as, also, an earnest for the future? Let us strive to remove defects, to correct abuses, and to improve, as fast as practicable, our system of instruction; but let us not be led into a disparagement of what has been done, and is now being done, in behalf of medical education.

A few words in conclusion, concerning characteristics which relate to medical ethics. At the Convention held in 1847, resulting in the organization of the American Medical Association, a code of ethics was adopted, and it has since been formally recognized as having binding force upon members of state and local societies throughout the Union. This code embodies rules which were in accordance with the usages of worthy members of the profession in this country, and with established ethical principles in other countries. It defines simply and clearly the line of conduct to be followed in the relations of medical men to each other and the profession at large, to their patients, to the public, and to those who, adopting a practice based on an exclusive dogma, or from unworthy acts, are not to be considered as professional brethren. This code has remained unaltered and with undiminished force for more than a quarter of a century. I state this fact as a characteristic which reflects honor on the representatives of American Medicine. I claim, in behalf of the Medical Profession of the United States, that the great majority of its members have been loyal to the code of ethics. With no penalty for violations of ethical rules beyond the loss of professional fellowship, a penalty which may be made subservient to selfish advantage, loyalty is secured by motives of self-respect, and regard for the power of the Profession. It may perhaps be claimed that in no other country is the line dividing legitimate and illegitimate medicine more distinctly defined than with us; and nowhere are instances of affiliation with irregular practitioners more infrequent. The same may perhaps be said of the number of those who, having once been in respectable professional standing, have yielded to the temptation of originating secret nostrums and patenting remedies or inventions. These characteristics are consistent with the fact that in no other country does the Profession of Medicine hold a higher social position or exert a greater public influence than in these United States of America.

Gentlemen, Members of the International Medical Congress: At this our Centennial Anniversary it has seemed to me appropriate to survey "Medicine and Medical Progress in the United States" from the points of view which excite feelings of gratification, hope, and faith. We should by no means shut our eyes to errors, defects, and short-comings; but there are other occasions more suitable for regarding these. The history of American Medicine for the past century contains much that we may rightly be proud of; we have no reason to be ashamed of its present condition, and need we doubt that the spirit of progress which has thus far guided it, will lead onward to the fulfilment of a glorious destiny!

ADDRESS ON HYGIENE AND PREVENTIVE MEDICINE.

BY

HENRY I. BOWDITCH, M.D.,

PRESIDENT OF THE STATE BOARD OF HEALTH OF MASSACHUSETTS.

Gentlemen of the International Medical Congress:

I have been requested to speak to you on Public Hygiene and its great resultant, State Preventive Medicine, as it appears to an observer looking back upon the Centennial Period now just closing.

As a measure of vital importance to the well-being of any community, and, as such, worthy to be cheerfully and amply sustained by great cities and States, Public Hygiene, as we now understand that term, has, till within a very short time, been wofully neglected, save when, under the stimulus of some great and terrible epidemic, frantic but temporary efforts have been made to stay the plague by Hygienic or by other means.

Of late, however, a new and better era seems opening to our view, and State Preventive Medicine affords us higher hopes for all coming time.

To this last, this noblest phase of Public Hygiene, its very gradual evolution out of the dogmatism and skepticism of the past, its present status, our duties relative thereto, and our golden hopes for its future, I crave your candid consideration during the brief hour I shall have the honor of addressing you. If, at the termination of my remarks, our foreign associates feel that I have given them but little information, and my countrymen find that I have said but little in praise of my country, one and all of you, I trust, will generously allow me the credit of having endeavored at least to speak the exact truth about the various States, and the United States as a Nation, in their relation to these matters. May I dare to hope that the plain unvarnished story of our present condition and short-comings, in regard to practical public hygiene, may do something to stimulate each State and the United States governments, to do more thoroughly the plain duties that lie open before them?

Before laying down the propositions I intend to defend, let me say we cannot, in the consideration of them, confine our view simply to this country, but must frequently refer to the men and ideas of other countries, as well as to those of our own.

And let me add that in citing the names of men who have been prominent here or elsewhere, I shall do so without intending either praise or blame, but simply as those of illustrious representatives of great systems of medicine or of wide currents of thought, upon which the greater part of mankind has been borne almost unconsciously along.

NATURAL DIVISIONS OF THE CENTENNIAL PERIOD.

In its Medical and Social ideas, the past centenary easily divides itself into three unequal epochs, viz.: I. From 1776 to 1832, the era of theory and of dogmatism; II. From 1832 to 1869, or that of strict observation,

and of bold, often reckless, skepticism; III. From 1869 to 1876, which is destined to continue and progress while the nation itself lives, the noblest and most beneficent of all, viz., that in which the profession, joining heartily with the laity and aided by the material and intellectual resources of great States, will study to unravel the primal causes of all disease with the object of preventing it. It is the epoch of State Preventive Medicine.

First Epoch, or that of Medical System-making, filled with an Overweening Confidence in our Art, with little or no Faith in the Vis Medicatrix Naturæ.

(From 1776 to 1832, or thereabouts.)

The influences which governed this period and the previous centuries, may be briefly sketched as follows: The illustrious Boerhaave began to enunciate his doctrines of disease at Leyden in 1701. His doctrines held sway in America until about 1765, or ten years before the opening of our centennial period. Following closely after him came Hoffmann, Cullen, Brown, and Darwin, and each with his own peculiar system.

Our ingenious and renowned countryman, Benjamin Rush, in 1790, proclaimed his own idea, viz., that a convulsive motion of the arteries is the proximate cause of all fevers, however different the causes may be.[1] Benjamin Rush was one of the most noteworthy men this centenary has produced, and as he had more influence than any other one person upon medical opinion during the first epoch; as he is called by one of his admirers "the American Sydenham," it seems to me not improper that I should on this occasion mention some facts of his life. He was born Dec. 24, 1745, on his father's plantation, fourteen miles from Philadelphia: consequently he was just entering the prime of manhood in 1776. Seven years before that, at the early age of twenty-four, he had been appointed Professor of Chemistry in the University of Pennsylvania.

During the Revolutionary war he resigned this professorship, and was made Medical Director of the Middle Department of the Continental Army. In 1789 he resumed his professorship of chemistry, and in October of that year became Professor of the Theory and Practice of Medicine, which office he held until his death in 1813. During all these years he energetically and ably defended his system, as he had previously upheld Cullen's. He has left accounts of various epidemics of yellow fever and other observations and essays, which are valuable as records of the period and as evidences of his intellectual and moral worth. He was essentially a medical system-maker like his predecessors. He believed fully in heroic remedies, and rather scoffed at Nature's influence in disease. His pupils spread themselves over some of the Eastern but more over the Middle, Western, and Southern States, carrying with them not only the wisdom but the errors of their great master. He thus had vast influence on the medical ideas of the country. This becomes still more evident when we remember that he held the chief professorship in the foremost medical school in the Union, and that, towards the end of his career, the number of students that listened to his eloquent and per-

[1] Rush's Med. Inquiries and Observations, Philadelphia, vol. iii. p. 11.

suasive tongue, amounted to about four hundred, annually drawn to Philadelphia from every part of the country.

The reputation of our profession among the more intelligent of the laity, when Dr. Rush was in his full glory, is brought out in the following extract from a letter from Thomas Jefferson to his friend Dr. Wistar in 1807. He writes, "I have myself lived long enough to see the fashions of Hoffmann, Boerhaave, Stahl, and Brown succeed one another like the shifting figures of a magic lantern, and their fancies like the dresses of the doll-babies from Paris; becoming from their novelty the vogue of the day, and yielding to the next novelty their ephemeral favor."[1] We may well fear that Mr. Jefferson's opinion of our profession was not much improved when Dr. Rush dogmatically proclaimed, during a heated discussion with some physicians of Philadelphia, that the time must and will come when the general use of calomel, jalap, and of the lancet without a physician's advice, will be considered "among the most essential articles of the knowledge and the rights of man"!

But Dr. Rush's theory and dogmatism were destined to fall under the influence of the fascinating theories of Broussais. Broussais was born in 1772, when Rush had already given evidence of his great powers as a teacher. This great Frenchman died in 1838, after his authority, which had been world-wide, had begun to decline. Broussaism spread widely in America, but less in New England, which had been trained more to close observation under the great masters in medicine, Dr. E. A. Holyoke, Dr. James Jackson, and others, than it did in the Middle, Western, and Southern States. In or about 1832, the system began to fall in America, as it had been previously falling in Europe. With its fall our first epoch terminates. The whole tenor of medical opinion during the period, as you readily perceive, with its theories and systems concocted in great minds, was not in the smallest degree suited to the growth of State Preventive Medicine.

Second Epoch; or that of Observation, and accurate recording and subsequent analysis of Facts; with an extreme confidence in Nature's power in Disease; a corresponding skepticism in regard to the use of Drugs; and, finally, dim presages of Preventive Medicine.

(From 1832 to 1869.)

The second epoch presents characteristics precisely the reverse of the first. Louis and his numerical method stand prominent in it.

Louis may be called the lineal scientific descendant of such men as William and John Hunter, Morgagni, etc. His nature rebelled against the dogmatism of the past, unsupported as it was by well-ascertained and recorded facts. You all know the great and wide-spread influence of his works in Europe; Broussaism fell before them. The epoch in America commenced when Dr. Gerhard, of Philadelphia, and Dr. James Jackson, Jr., of Boston, and other pupils of the observation school, returned to America. Drs. Gerhard and Jackson had high mental powers finely cultivated. Both came back devoted friends, and admirers of Louis as a man and as a medical reformer. They were full of the new ideas, and enthusiastic defenders and expounders of them. The influence of these

[1] Works of Thomas Jefferson, Washington, 1854, vol. ix. p. 107.

ideas on the currents of medical thought in America was immense. It extended gradually over the whole country.

It must be admitted that at times there was something unwarrantably supercilious in the terms in which some of Louis's disciples, rather than Louis himself, spoke of the past. It seemed as if they would, if they could, wholly ignore the past in their desire to build up the medicine of the present and of the future upon the firm basis of strictly recorded fact. By this exclusive spirit of many of the "Numerical School," while infinite good has been done, a great apparent evil to practical medicine has arisen. I allude to the more or less complete skepticism on the part of many of the profession, and of the laity, in regard to every species of medical treatment, except perhaps that of good nursing. The pendulum of human thought, as always happens in such cases, has swung far beyond the line of exact truth, so that from a blind faith in the supreme power of our art, noticeable in our first epoch, many have passed into an equally blind and fanatical skepticism in reference to it. Nevertheless I presume all will admit that Louis's school was needed to sweep away all false systems unsupported by well-recorded and sufficiently numerous facts.

Louis's doctrines, though vehemently opposed by some who had grown old under the previous epochs, were received by most young men with joy, and philosophical minds among the elders were charmed with the accuracy observable in Louis's Numerical Method, as shown in his writings. Under the direct or indirect influence of his writings and Numerical Method, which Dr. Guy[1] considers the guiding power of the present time, a very large number of independent observers and workers have been educated in this country and in Europe. The mottoes selected by Louis as his own guides are identical with those of modern science.

In addition to the specific disciples of Louis, there were three others, all men of great intellectual ability, who by their writings and teachings powerfully influenced this epoch. I allude to Jacob Bigelow and Elisha Bartlett, of America, and John Forbes, of England. Two of this trio are now dead. Dr. Bigelow entered his 90th year last February. His life nearly spans the century, and as it closely unites the first and second epochs, I hope you will permit me to allude to him somewhat as I did to Dr. Rush. He was born February 27, 1787; that is, two years before Dr. Rush resumed his professor's chair in the University of Pennsylvania, at the close of the Revolutionary war. After a most honorable and successful life as a physician, and as professor of the Harvard Medical School, Dr. Bigelow has been, for years, totally blind, and hopelessly unable to move from his bed for more than eighteen months. To a casual visitor he seems as bright and as witty as ever, while his beautiful and uncomplaining submission to what most persons would deem a sad fate, raises him in the eyes of all beholders even higher than he was at the period of his greatest energy and fame. A visit to his bedside affords a delightful sense of repose from the bustle of daily toil. It was my happiness to have a long conversation with him a few months ago. I found he retained a vivid reminiscence of the days of his youth. He was one of Dr. Rush's class, and bears full testimony to the eloquence and earnestness with which Dr. Rush advocated his medical theories more than half a century since, and only a few years before he died.

[1] Public Health; Wm. A. Guy, M.B., F.R.S., London, 1874.

Dr. Bigelow fully sustains me in my position relative to Dr. Rush's views of Nature and of our Art.

Dr. Bigelow's influence upon this second epoch was diametrically opposed to Dr. Rush's, during the first. Dr. Bigelow earnestly supported the principles and methods advocated by Louis and the Numerical School. By his writings and teachings he had great power over New England directly, and indirectly over the medical opinions of the whole country, by means of his pupils, who migrated to our most distant States. The skepticism of Louis's School was augmented thereby.

Whilst Dr. Bigelow was thus sapping our faith in drugs, or rather in the polypharmacy which had come down to us from the past, there was sent forth from the chief medical journal of that day, viz., The British and Foreign Medical Review,[1] and apparently under the sign manual of its able editor, John Forbes, one of the boldest avowals of the same creed. I allude to Dr. Forbes's article entitled "Homœopathy, Allopathy, and Young Physic." Admired by the few, ignored or violently opposed by the many, it has nevertheless stood the test of time, as one of the strongest of protests against the drugging of the day, and an eloquent defence of the power of Nature in the treatment and cure of disease.

Notwitstanding my high estimate of this manifesto by Dr. Forbes, I think that very few young men would be led by it to the study of our most noble profession. It is too destructive of all earnest faith in our art. It was, however, exactly what was needed at the time. The polypharmacy of a past age then and there received its most deadly blow. Nature and her powers were glorified. And no one who reads carefully the record of the preceding time can doubt that such a blow was needed previously to our entering upon a new phase of development of medical science, expressed by the term State Preventive Medicine. Dr. Forbes, indeed, frequently and in glowing terms, hints at the "reformation" that is impending. He is no prophet, although he sees dimly, what is to be "the result of mature reflection, and of the labor of many years and many hands" (p. 262); "we must," he says, "direct redoubled attention to hygiene, public and private, with the view of preventing disease on a large scale." "Here the surest and most glorious triumphs of medical science are achieving and to be achieved" (p. 263).

The third individual, who by his writings and as a teacher, seems one of the noblest types of men of this epoch, is Dr. Elisha Bartlett. He was undoubtedly one of the most philosophical medical men America has produced during the Centenary. And his heart was devoted to medical reform. He was born at Smithfield, R. I., in 1805, and died July, 1855.[2] He practised the profession for some years in Lowell, Massachusetts, and was respected as an able and most accomplished physician. He felt, however, as he said to me, "called to teach." He was soon summoned to the chair of Theory and Practice at Pittsfield. Subsequently he held a professorship at Dartmouth College, New Hampshire; at the schools at Lexington, and at Louisville; subsequently at Baltimore, and finally at New York, in the University and with the College of Physicians and Surgeons.

From these various chairs he was able to influence North, East, South, and West of our country. He was an admirable and attractive teacher, winning belief by his earnestness, his fairness of statement, and fasci-

[1] British and Foreign Med. Rev., vol. xxi. p. 502.
[2] Appleton's Cyclopædia.

nating address. Though not educated under Louis, he thoroughly appreciated his methods and his writings, and proclaimed them as the dawn of a new and great era in the history of medicine. In Dr. Bartlett's Philosophy of Medical Science, published in Philadelphia in 1844, he says "that to find out the best methods of preventing, of modifying," as well as "curing" disease (page 287), "is the great mission which lies directly before us, and this is to constitute the great work of the next and of succeeding generations." He, in these words, appears as one of the prophets of the present epoch, now in its infancy, which delights and encourages us rather by its anticipations than by its actual accomplishments.

Thus with beautiful prophecies for the future, I close the list of men whom I deem most prominent in carrying forward the ideas underlying this second epoch. But no one of them saw what we now see. Their mission was chiefly destructive, or constructive only in some degree of the natural history of disease. The general tendency of their writings, so far as they bore upon medical practice, was to utter skepticism not only in regard to the manifest absurdities of our fathers, but likewise in reference to the good things suggested by them. Although they sometimes, as we have seen, hinted at prevention of disease, they did not dream of the noble idea of State Preventive Medicine in its widest scope which has already commenced in various States of this country, and among the nations of Europe. Their skepticism, like all skepticism, was chiefly iconoclastic. We need faith in an idea before we can build it up in actual life. Such a faith we shall see breaking out in our third and last epoch, and to this I now call your attention.

But before proceeding to speak of it, let me make two remarks, which I regret to feel compelled to submit, but for their truth I can vouch from my own professional experience of nearly half a century:—

First. The medical profession as a body has heretofore taken very little interest in the ideas underlying preventive medicine, and hygiene, private or public. This must be patent to every one of us. We all know how few sanitarians there have been among us until very recently, and how little they have been to our taste. I confess myself to have been a most decided sinner in this matter. It is proved likewise by the almost total neglect hitherto of physical culture in our schools and great seminaries of learning. I know of but one medical college in which there is a full professorship devoted to hygiene. The Harvard Medical School, which has made great advances in medical instruction within the past ten years, has only a lecturer, and as I learn from students now at the school, and who for some few years past have been there, the subject is scarcely known, as compared with other branches of medical learning.

Second. We owe to the laity, rather than to the profession, the first and strongest efforts in behalf of State Preventive Medicine.

Third Epoch; or, that in which the Medical Profession is aided by the Laity, and the idea of State Preventive Medicine fairly inaugurated, as marked by the Legal Establishment of the first State Board of Health.

(From 1869, and which will reach into the far-off future.)

The ruling idea of this epoch is still in its infancy, but it shows by what it has already accomplished, trivial though that performance may

seem, at first glance, to be, its inherent, great, and nascent power. Its objects are vastly wider than those of any preceding epoch. Its destiny is as fixed as that of the steam-engine, the telegraph wire, the locomotive, or the use of anæsthetics. I cannot foresee a time when the ideas underlying it will not be held in esteem and acted upon for the welfare of mankind.

Among the men who stand prominent in their relations to this epoch, and in connection with the English speaking race, are two laymen. One of them I fear may be but little known to most of my hearers, or even to the people of his native State: I allude to Lemuel Shattuck, of Boston. The other is Edwin Chadwick, a Barrister of London, for many years known and honored by every civilized nation as one of the ablest and most earnest of sanitarians.

Mr. Shattuck, in 1850, presented to the legislature of Massachusetts, a most exhaustive State Paper entitled, "Report of the Sanitary Commission of Massachusetts." In that document are laid down all the principal ideas and modes of action which underlie the present sanitary movements in Massachusetts, and I think I may also add in America. By this document were laid deep in the second epoch the fundamental ideas of the third. It was seed well sown, but destined to lie dormant for nearly a quarter of a century.

The report fell flat from the printer's hands. It remained almost unnoticed by the community or by the profession for many years, and its recommendations were ignored. Finally, in 1869, a State Board of Health of laymen and physicians, exactly as Mr. Shattuck recommended, was established by Massachusetts. Dr. Derby, its first secretary, looked to this admirable document as his inspiration and support. In giving this high honor to Mr. Shattuck, I do not wish to forget or to undervalue the many and persistent efforts made by a few physicians, among whom stands pre-eminent Dr. Edward Jarvis, and occasionally by the Massachusetts Medical Society, in urging the State authorities to inaugurate and to sustain the ideas avowed by Mr. Shattuck. But there is no doubt that he, as a layman, quietly working, did more towards bringing Massachusetts to correct views on this subject than all other agencies whatsoever. Of the second layman, Mr. Edwin Chadwick, I need say nothing. You all know him. Fortunately for himself, he has lived to see rich fruits from his labors. That was not granted to Mr. Shattuck.

But other influences have been at work tending to the same end. Europe has influenced us more than at any preceding time. France long since entered on a career of study and of publication on public health. The *Annales d'Hygiène Publique* are proof of this. The labors of Parent-Duchatelet are recognized by all. The zeal of Quetelet, of Belgium, has been like a household word everywhere among the laity and profession in every civilized State. Pettenkofer, of Munich, more recently has labored successfully in the same field; and, still nearer to the present, comes up that extraordinary genius, Virchow, of Berlin, great in every department of science or of State upon which he enters. But by far the greatest influence has been exerted upon us in America by England, who, by her unbounded pecuniary sacrifices and steady improvement in her legislation, and her able writers, has far outstripped any country in the world in the direction of State Preventive Medicine. I think I may, with perfect truth, say that the consummate skill in the discovery, removal, and prevention of whatever may be prejudicial to the public health, shown under the admirable direction of Mr. Simon, late Medical

Officer of England's Privy Council, by his corps of trained inspectors, is wholly unequalled at the present day, and unprecedented, I suspect, in all past time in any country on the globe.

In this country the papers published more recently by several of the State Boards of Health, have tended to interest the whole community on the subject of public hygiene. The number of single laborers in the same field is daily augmenting. The United States Government, by its Army and Navy publications, previous to, during, and since the late Civil War, has done a vast sanitary work. The library and museum in the Surgeon General's Department at Washington, commenced during the horrors of that contest, are also invaluable in the same direction. If they be hereafter thoroughly sustained by the government, as in the past, we cannot estimate the great advantage that will arise in all departments of medicine, and in none more than in that of public hygiene.

As the Crimean war taught the world very much in reference to this subject, so our war, dreadful as it was to both parties, was the means of bringing into life several most beneficent institutions which were never before thought of, or at least never carried out on so grand a scale. I allude to the Sanitary and Christian and Western Sanitary Commissions of the North; to the Wayside Hospitals, Christian Relief Associations, and State Hospitals at Richmond, etc., of the South. Through these, money and food were distributed without stint to the sick and wounded, often to foes as well as friends, wherever found, either on the battle-field or in hospital. We can never know how many human lives were saved, or how much torture prevented, by the agents of these noble institutions on both sides of the line of battle. But we can estimate how much the desire to save life, prevent disease, and promote health, and to provide some of the means for so doing, were, under their blessed influence, instilled into the minds and hearts of our people from Maine to Texas.

Great strides in Public Hygiene were also made during the war, by the fact that the people outside the military lines, and the officers and soldiers within them, very soon began to learn, by dire experience, or by the urgent appeals of experts in Sanitary matters, the all-important advantages of cleanliness, sobriety, and strict methods of action, as opposed to the distress consequent on filth, intemperance, and chaotic rule; and we cannot doubt that every surgeon, whether National or Confederate, who served during the war, became more practically versed in the advantages of prevention of disease than he was before. All that knowledge is now brought back to civil life.

The *National Quarantine Conventions*, so called, had also important influence. Four were held before the breaking out of the war, viz.: in Philadelphia, 1857; in Baltimore, 1858; in New York, 1859; and in Boston, 1860. The war closed their labours. From the eminent persons engaged in them, and attendants at the meetings, and the characters of the papers published, there can be no doubt that they contributed very much to lead the public mind to the ideas prevalent at the present time.

In April 18, 1872, was held the primary meeting whence has sprung the successor of the National Quarantine Conventions, above alluded to. I refer to the *American Public Health Association*, which has held meetings in New York, Philadelphia, and Cincinnati; and will this autumn hold its session at Boston. Able papers have been published by it on various Sanitary matters, on the transmission and prevention of disease, on quarantine, longevity, hospital hygiene, etc.

The *American Social Science Association* has, of late years, done most valuable work in the same direction.

Among the more strictly professional institutions that have helped forward the cause of Public Hygiene and Preventive Medicine, may be named the *American Medical Association.* In 1847, this Association was instituted, and almost from its inception, it has annually published papers relating to our subject, and still more recently very earnest efforts have been made by some of its members to obtain a definite National Health Organization from the United States Government. The frequent intermingling of men, brought about by this Association, from all parts of the Union, has contributed to the same end. It must be confessed, however, that, judging from the small number of members attending the Section on Hygiene, that subject seems to afford less interest than any other.

Finally I may assert that, during the past three or four years there has sprung up in many parts of the country, a wide-spread thoughtfulness about the necessity and value of hygienic measures. Almost all persons in their various spheres, have become more accessible to the protests of the sanitarian. Still further, it may be asserted that during this last epoch, short as it is, more practical work has been done among the people, tending to prevent and crush out disease, and more valuable papers written, illustrative of Public Hygiene, the world over, than since the Christian era began. In every State there are active and earnest laborers in this field, and their number is daily increasing. It would be impossible on this occasion, to name even a tithe of them. Some States in their corporate capacity, have sustained these workers for the public good. But I regret to say a large majority of the States and Territories of this Union are not yet sufficiently enlightened to appreciate the duty devolving on them to be careful of the health of their people.

With these general historical remarks on the gradual evolution of State Preventive Medicine and Public Hygiene, during the past centennial period, I now pass to the consideration of the actual condition of the Country at the present time with regard to these all-important topics.

THE PRESENT CONDITION OF STATE PREVENTIVE MEDICINE IN THE VARIOUS STATES, TERRITORIES, AND THE NATION.

Several months ago I issued a circular containing several questions bearing on this subject, and tending to elucidate it as far as I thought I could do so with the means at my command. Doubtless, to critical eyes, objections may be made to the small number and to the relevancy and character of the proposed questions. It appeared to me, however, that a few interrogations, all or most of them, answered, even monosyllabically, from all quarters of the Country would enable the inquirer to get a glance at the present condition of Public Hygiene and of State Preventive Medicine better than he could from any large number, very many of which would not be answered at all from some of the States. The paper was sent to two hundred and sixty-seven (267) medical men living in the thirty-eight States, nine Territories, and the District of Columbia,

making in all forty-eight governments. These embrace an area covering (25°) twenty-five degrees of latitude and (47°) forty-seven degrees of longitude, between the Atlantic and Pacific Oceans. In the South they lie almost in the tropics; at the North they reach close to the coldest inhabitable portion of the Globe; in all embracing an area of 3,603,884 square miles.

Of the character and ability of my correspondents, I would say that I tried to select the ablest men, and, as far as possible, those known or supposed to be interested in Public Hygiene; representative men, in fact, resident in the various regions. I may have failed to apply to all who perhaps would have willingly answered my questions. If, however, I have selected with any accuracy, I think you will admit that their various reports will together constitute as full and as accurate a statement of the whole matter, so far as my questions cover it, as it is possible for me, without governmental aid, to obtain. Replies have come from one hundred and sixty-seven (167) physicians, residents in every State and territory except the Indian Territory, which last is a reservation held still in an unorganized state as the residence of Indians, in various conditions from barbarism up to a low civilization, and where ideas of Public Hygiene are little thought of.

Analysis of Correspondents' Replies.

First Question.—*Does your State by its legislation show a due appreciation of the duty devolving upon a State to be careful of the health of its people?*

I considered this a fundamental question. The answers from the forty-eight States and Territories were as follows:—

Thirty-four,	(34)	No.[1]
Eight,	(8)	Yes.[1]
Four,	(4)	Indefinite.[2]
Two,	(2)	No Reply.

In other words, of the forty-eight governments in this Union, thirty-four (nearly three-quarters), by their legislative acts, have, according to correspondents resident therein, shown but little care for the health of their people. Among those thus failing in duty, appear the great States of New York and Pennsylvania; I cite these two, not in invidious distinction, but simply because they have been the chief States of our Union since Colonial times, and because they hold that proud position now. Moreover, it will be admitted by those States which have replied affirmatively (1) that it is only within six or eight years that they have shown any marked interest on the question of State Preventive Medicine, and (2) that the number of deaths from preventable diseases, in every State, is still frightfully great, which ought not to be the fact if these States had really shown, for any length of time, this due appreciation claimed for them by my correspondents. Let not us, however, who have traced the very gradual evolution of the idea of State Preventive Medicine during the past centenary, wonder at this apparent neglect of Public Hygiene, shown by the various States; let us rather rejoice at even this small awakening of the public interest upon these matters, wheresoever a European civilization has any foothold.

[1] Yes or No means that a unanimous opinion was returned by all correspondents in the State or Territory.

[2] This term is used when the opinions of correspondents were not unanimous on any question.

SECOND QUESTION.—*Is the State willing to expend money* (a) *to support State or Local Boards of Health?* (b) *to carry out Scientific Investigations as to the causes of Disease?* (c) *to repress noxious or offensive trades?* (d) *to prevent adulteration of food?* (e) *to prevent the Cattle Disease? or* (f) *to carry on any other investigations tending to promote Public Health, or to prevent ill Health?*

The touchstone which tests the earnestness of an individual or of a Nation in reference to any subject, is a willingness to spend money in furtherance of it. Tested by this talisman, how stands our Country in reference to Public Hygiene and State Preventive Medicine? Let us look at the answers to the above questions.

Is the State willing to spend money (a) *to support State or Local Boards of Health?* The following answers were received from correspondents.

Thirty-six,	(36)	No.
Ten,	(10)	Yes.
Two,	(2)	No Reply.

The fact here brought out is that three-quarters of all the governments of this country are unwilling to spend money to support a State Board of Health. Now I contend that the legal establishment of such a Board is the first step towards any definite sanitary organization in a State, and the fact that so many States have done nothing towards the formation of such Boards, or when legally established, have refused to pay money for their ample support, plainly shows the very small advance yet made by this country on these vital questions. Still, further, if we look at the States from which an affirmative reply has been received, we shall find that only very recently, since 1869, have any such Boards been established, and generally that the amount of money appropriated for their support is small, compared with what is spent in other departments of government vastly less important to human welfare.

Is the State willing to spend money (b) *to carry out Scientific Investigations as to the Causes of Disease?* The following are the replies:—

Thirty,	(30)	No.
Twelve,	(12)	Yes.
Five,	(5)	Indefinite Reply.
One,	(1)	No Reply.

Thus thirty governments out of the forty-eight are reported as being unwilling to spend money for the scientific study of the causes of disease. Twelve reply affirmatively. But from several of these we find some qualifications of answer, *e. g.*, "rather unwillingly," or "not much," or "when importuned," or "to a limited extent." Some of the foremost decline to make grants for special investigation. One of the most known and respected Sanitarians in the Union declares that his State "grants as much as is asked for," which fact, coupled with a second one, viz., that his State has not yet established a State Board of Health, seems to support the idea that he and his medical associates are at fault: Does the State even now need an efficient layman to stir it up to efficient action? Only during the past year, has Massachusetts done anything in this precise direction, viz., when it appropriated ten thousand dollars ($10,000) for the investigation of the question of the Pollution of Streams. As I had nothing to do with the making of that report, and as the majority of the committee having it in charge, was selected as the ablest men who could be found, though residents of other States, I feel at liberty to express the opinion that the sum expended was infinitely small in comparison with the very valuable and exhaustive report made;

a report which will be of importance to every other State undertaking the same or similar trains of investigations.

Is the State willing to spend money (c) *to repress noxious or offensive trades?* The following answers were made:—

Twenty-six,	(26)	No.
Fourteen,	(14)	Yes.
Seven,	(7)	Indefinite Reply.
One,	(1)	No Reply.

A priori, one would consider this a most legitimate and imperative duty of a State to so govern noxious and offensive trades that they should not bring ill health to the people, yet it appears that more than half of the States do nothing. Fourteen only seem attempting to do something. In this connection I cannot help referring to some results in Massachusetts.

The town of Brighton is beautifully situated in an undulating country, within easy access of Boston, and as such admirably fitted for residences of the business men of the city. This beautiful suburban district was, only a few years ago, a disgusting place, in consequence of about fifty vile smelling and filthy looking slaughter houses, which were dotted all over the township. No one could drive or go by rail through it without offence, and at times almost nausea. New slaughter houses were daily springing up. Under the influence of a law, empowering the State Board of Health to attend to the matter, and giving it very wide power, every private slaughter house has been swept away within the past eight years. A very large, cleanly conducted abattoir, which burns up in a great measure, if not wholly, its own noxious odors, and which is built a little distance from the village, now includes the whole of the individual slaughter houses above named. One can now drive in any direction without offence to eye or sense of smell. Meanwhile, the price of land has more than doubled in value. Before this was brought about, however, many hearings and personal examinations were made by the Board. Eminent lawyers appeared and protested against its proceeding under the extraordinary powers which the legislature had given it, and which those advocates said were unconstitutional, because, as they contended, contrary to the "Bill of Rights" of Massachusetts.

The Court, however, when appealed to, always sustained the decisions of the Board, and once it threatened a contumacious butcher, who refused to obey, with imprisonment for contempt. For these reasons and for others that might be named, I heartily commend the law, as it stands in Massachusetts, as worthy of consideration by those who wish to control noxious trades in other States.

Is the State willing to spend money (d) *to prevent the adulteration of food?*

Twenty-three,	(23)	No.
Sixteen,	(16)	Yes.
Seven,	(7)	Indefinite Reply.
Two,	(2)	No Reply.

Certainly an extraordinary result, but one which possibly might have been anticipated, when we remember the widespread system of sophistication and adulteration known to exist among us. Rapidity and quantity of work rather than excellence are sought for. When Public Hygiene is duly thought of, and State Preventive Medicine has full sway, the adulteration of the food of the people will be deemed one of the most heinous of crimes. Practically, now it is allowed to flourish unrestricted in the majority of the States, even in those which have laws intended

to prevent it. Europe is undoubtedly far in advance of America on this subject.

Is the State willing to spend money (e) *to prevent the cattle disease?* The following answers were received:—

Twenty-one,	(21)	No.
Ten,	(10)	Yes.
Sixteen,	(16)	Indefinite Reply.
One,	(1)	No Reply.

(For remarks on this subject see Question Sixth.)

Is the State willing to spend money (f) *to carry on any investigations tending to promote public health or to prevent ill-health?* The answers were these:—

Twenty-eight,	(28)	No.
Ten,	(10)	Yes.
Nine,	(9)	Indefinite Reply.
One,	(1)	No Reply.

That is, one-half the governments seem unwilling, and less than a quarter claim to be willing to spend money for this purpose. This seems a most natural consequence to all preceding answers.

THIRD QUESTION.—*Has your State established a State Board of Health? If so,* (a) *when was it established?* (b) *What amount of annual appropriation is made for its support?* (c) *Are any occasional grants made for specific investigations?* (d) *Has the Board any organized body of correspondents throughout the State?* (e) *What executive powers have been given to the Board in reference to local nuisances or noxious trades?*

Some of these questions have been fully or partially answered already. I shall in this place summarily include them in one answer as follows: Twelve only of these States have State Boards of Health. The first one was legally established in Massachusetts in 1869. It operates equally over every portion of the State. The amount of money paid, as I have already stated, is small considering the wealth and population of the State. For special purposes, Louisiana and the District of Columbia have at times spent large sums. Not a single State has as yet a perfect list of correspondents or inspectors. Massachusetts has done much in this direction, and is annually improving her position by selecting the ablest men, physicians or laymen, who can be found in the various towns.

The position of correspondent of this Board is frequently considered an honor, though there is no pay attached to the office, and often it is no sinecure. In reference to executive powers given to the Board, it cannot be said that any State Board has plenary powers, as town Boards have, in some States. It is, perhaps, well that their duties should generally be advisory merely, on certain occasions only having plenary powers conferred upon them, and with the right to appeal to the Courts to sustain their decrees, whereby the moral force of the Boards is materially augmented.

FOURTH QUESTION.—*Have County Boards of Health been established by law?*

The answers are—

Twenty-three,	(23)	No.
Four,	(4)	Yes.
Seven,	(7)	Indefinite Reply.
Four,	(4)	No Reply.

That is, only four of the States report affirmatively. Evidently the necessity of such Boards is not admitted. Yet I cannot but think that eventually, when Public Hygiene shall have its thorough organization, these County Boards will form an integral part of it; certainly in the Southern, Western, and sparsely settled States.

FIFTH QUESTION.—*Have any Town Boards of Health been established by law?*

The answers are—

Eight,	(8)	No.
Fourteen,	(14)	Yes.
Twenty-two,	(22)	Have them by local or municipal rather than state law.
One,	(1)	Indefinite Reply.
Three,	(3)	No Reply.

Which replies, as I understand them, intimate that in one-half of the governments many towns have established, by their inherent right of self-defence, local Boards of Health without first appealing to State Authority.

SIXTH QUESTION.—*Has the State passed any law leading to a thorough and definite improvement of the Public Health?* (a) *by a Sanitary Survey of the State?* (b) *by a law for the registration of Births, Deaths, and Marriages?* (c) *If so, how long has it been in operation?* (d) *Has the Registrar been able to draw from such records any law governing the Public Health?* (e) *Has any law been passed relating to drainage of land?* (f) *to irrigation?* (g) *to checking the influence of rivers by levees?* (h) *to the introduction of water into cities?* (i) *to the prevention of contagious diseases?* (α) *Smallpox?* (β) *Cholera?* (γ) *Yellow Fever?* (δ) *Cattle Plague? etc. etc.*

It is impossible on this occasion to consider all of these questions. I shall make selections from the answers which will best illustrate my main subject.

(a) *By a Sanitary Survey of the State?* The returns are as follows:—

Forty,	(40)	No.
None,	(0)	Yes.
One,	(1)	Indefinite Reply.
Seven,	(7)	No Reply.

One would suppose that this would be one of the first questions asked by the settlers of a new country, and yet, judging from our returns, not one of the States in this Union has ever made such a survey, save perhaps indirectly in connection with some matter of trade or a geological or other examination for the purposes of gain. Doubtless very grave mistakes have been made in consequence of this neglect. Considerations of trade and personal safety from external danger have too often decided the question of the site of a town. It is to be feared, moreover, that with the keenest examination of a locality, the emigrant, upon a new and virgin soil, would be unable to decide the question. For often, not until months after the plough has passed through it, and the colony has become firmly established, does the deadly malaria show itself. But when a State has arrived at sufficient strength and power to be able so to do, it would seem that a thorough Sanitary Survey should be considered the first of duties. And yet I doubt if any State Legislature of this Union, at the present time, would for a moment consider the question. It would be deemed a *useless expense!* The people will demand it ere long.

(b) *By a law for the registration of Births, Deaths, and Marriages?*

Sixteen,	(16)	No.
Twenty,	(20)	Yes.
Eight,	(8)	Indefinite Reply.
Four,	(4)	No Reply.

That is, one-third definitely declare that this fundamental law, upon which all vital statistics are founded, has never been passed. Twenty, less than half, have such a law. But eighteen out of the twenty use various qualifying phrases in regard to the character or enforcement of the law, *e. g.*, "imperfect," "not carried out," "defective," "no regular registration," "carried out only for certain great cities." In one it is "a dead letter," and in another "not enforced;" others have it "a farce," or that "it was enforced before the late war." Some have "only marriages," some "only deaths."

The sum total of the matter is that only two States have made affirmative replies without special qualifications. Knowing what I do of one of these, viz., Massachusetts, I cannot claim that to be perfect in many respects. If, turning from the States, we look at the United States censuses, we find the same short-comings. For further remarks on this topic I refer to Question Eighteenth; remarks by Messrs. Walker and Elliott.

No one can regret more than I do the necessity of stating these facts. May the sting of their severe truth, stimulate us and our children to better work in the coming centuries!

(c) *If so* (*that is, if a registration law has been enacted*), *how long has it been in operation?* After the facts stated in regard to the last query, the further question of time seems unimportant. It is evident, however, that for the last ten or twenty years only, have State Registrations been carried on in a very few States, although some of the larger cities have had imperfect returns for a much longer period. The United States Government has had decennial censuses since 1790. To judge of their value in certain respects, we have simply to look at the remarks made upon them by the superintendent of the last. (*Vide* Question Eighteenth.)

(d) *Has the Registrar been able to draw from such records any law governing the Public Health?* I shall make my remarks in connection with this subject, under the last question of the entire series.

(e) *Has any law been passed relating to the drainage of lands?*

Twenty-four,	(24)	No.
Seven,	(7)	Yes.
Six,	(6)	Indefinite Reply.
Eleven,	(11)	No Reply.

That is, one-half report that nothing has been done by the State. Only one-seventh report affirmatively. But I do not understand that in any case such a drainage was made for a sanitary object, but rather to improve the land for agricultural purposes. How much the Sanitary, Physical, Moral, or Intellectual wealth of a people is wrapped up in simple drainage of the land, we may judge from the glowing account given by my correspondent, Dr. Breed, at Princeton, Illinois. By that it appears that no less than 36,000 acres of land lying in one mass, and comprehending at least half of three counties in Illinois, were drained by the State, with the most gratifying results upon the health and character of the settlers thereupon. Moreover, a great sum accrued to the Common School Fund of the State, from the enhanced value of the land for all purposes. One cannot but recommend the example of Illinois to the consideration of the Legislatures of many of her sister States.

(f) *Has any law been passed relating to irrigation of land?* The answers are:—

Thirty-one,	(31)	No.
Five,	(5)	Yes.
Five,	(5)	Indefinite Reply.
Seven,	(7)	No Reply.

All the affirmative replies except one, viz., Utah, report that it was done for "Agricultural Purposes." Apparently no one thought of Health in connection with it. Even Utah probably was induced to irrigate more by its actual wants than by any thought of Sanitary improvement. Near Salt Lake, which itself is utterly impotable, pure water was of prime necessity for two imperative reasons, viz., for culinary purposes, and for agriculture. What the Moors did for Granada, the Mormons have, to a certain extent, done for our American Desert, by their "thousands of miles of ditch under a general law," as my correspondent graphically, if not scientifically, describes the immense work done by this people.

(g) *Has any law been passed relative to checking of rivers by Levees, etc?* The answers are:—

Twenty-eight,	(28)	No.
Four,	(4)	Yes.
Five,	(5)	Indefinite Reply.
Eleven,	(11)	No Reply.

In proposing the question, I had my mind chiefly on the great cities situated upon our mighty Mississippi, and its various tributaries. Eventually, it would apply to other rivers, like the Yellowstone and others. In various parts of the land, I regret that my correspondents enable me to state but little in reference to sanitary measures connected with the question. It is evident that New Orleans, *e.g.*, depends for its very existence upon them. Correspondents from Arkansas state that some levees have been made for agricultural purposes, and one adds significantly, "but it has improved the land and the health of the people living near the place."[1]

(h) *Has any law been passed for introducing water into cities?* The answers are as follows:—

Twenty-three,	(23)	No.
Fourteen,	(14)	Yes.
Four,	(4)	Indefinite Reply.
Seven,	(7)	No Reply.

Indiana and Pennsylvania have general laws upon the subject. Probably all the States have permitted, either by general or special statutes, this introduction of water, because of its prime necessity. More particularly within the last ten years have towns and cities waked up to the propriety of introducing fresh water from distant sources, in order to avoid the evil results of the possible contamination of wells from privies, etc., in the immediate neighborhood.

But it is a singular fact that while thus bringing in *new* water, cities

[1] In the very able and interesting report of the United States Bureau of Topographical Engineers (Philadelphia, 1861), prepared by Capt. A. A. Humphreys and Lieut. H. S. Abbott, U. S. A., on the Physics and Hydraulics of the Mississippi River, etc., it is suggested that, eventually, there should be a uniform and scientifically constructed system of levees for that river, from the Ohio to below New Orleans (p. 417, etc.). Surely such a plan would be worthy of the nation, and, under the idea of its value to commerce between the several States and foreign nations, would it not be legitimate national work under our Constitution?

have not often scrutinized its exact purity, nor have they sufficiently provided against its future impurities. Boston, Albany, and I fear Chicago and Philadelphia, and I doubt not many other cities in this Union, might be cited in proof of the truth of this proposition. Some of these cities have wholly ignored the warnings of sanitarians in this respect, listening to selfishness and political partisanship, rather than to the dictates of Hygienic Law. As they have sown the wind, so, at some future time, they will doubtless reap the whirlwind, if an epidemic like Cholera should sweep over the land.

(i) *Has any law been passed relative to the prevention of contagious diseases?* (α) *Smallpox.* The answers are:—

Sixteen,	(16)	No.
Twenty-one,	(21)	Yes.
Seven,	(7)	Indefinite Reply.
Four,	(4)	No Reply.

There must be some error here, for I cannot think that sixteen of the States have, as yet, passed no law relative to smallpox. And yet from the way in which the laws on this subject are neglected, or limited of operation even in those States which claim that they have proper laws; and from the fact that we have smallpox epidemics all over the country constantly prevailing, which could easily be prevented by vaccination; from all these facts, I feel sure that great ignorance and carelessness on the subject are to be found everywhere in this country. The recent events in Montreal, relative to vaccination, in which a mob of infuriated and ignorant men attacked and over-awed the Common Council of the city, show what might happen in these States.

A late city physician of Boston, used to declare that he could keep Boston free from smallpox if he could prevent the citizens from meeting immigrants from Maine, who flocked, most of them unvaccinated adults, into the city limits. This assertion, though not perhaps strictly true, I have no doubt is partially so, and it illustrates an important fact, viz.: that it is indeed impossible for one State to free itself from this scourge, until the United States shall, by a general law, require that every child born shall be vaccinated at a very early period, and afterwards occasionally revaccinated. Yet more, we shall never be free from it until every foreign nation shall adopt the same method, and an international code of health in this respect shall have been established. Though such a code may be in the far future, it must eventually come, not only in reference to smallpox, but in regard to every other pestilential scourge of our race.

(β) *Has any law been made relative to the prevention of Cholera?* The answers are:—

Twenty-one,	(21)	No.
Sixteen,	(16)	Yes.
Four,	(4)	Indefinite Reply.
Seven,	(7)	No Reply.

Entirely similar reports came in regard to this disease as in regard to smallpox; all indicate a "*laissez aller*" method in regard to it, so that if the cholera were to strike any State at the present time, there is probably not a town in the land which would not be liable to fatally suffer from its ravages in consequence of "filth"[1] within the town limits.

[1] Used in its broadest signification. Simon on "Filth Diseases and their Prevention." *Vide* Report of Medical Officer of the Privy Council and Local Government Board (Eng.), New Series, No. 2. Reprinted in Boston, Campbell, 1876, under the direction of the Massachusetts State Board of Health.

But the United States Government, through the War Department, has recently published an invaluable history of cholera in this country. By this volume alone we can judge of the immense importance to the whole country, a central power, such as I have suggested above, would speedily become. It would grasp the whole country in one mass, rather than as separate States, and immensely broader, almost cosmic views of disease would be thereby given instead of those derived from detached local observations. In order to gain this desirable end we need a National Health Council composed of representatives from each State, and a Secretary of Health, the peer of other Secretaries in the National Cabinet.

For further elucidation of my views on this subject, I beg leave to refer to my address delivered before the American Medical Association at its session in Louisville, in 1875.

(γ) *Has any law been passed relative to the prevention of Yellow Fever?* The answers are:—

Twenty,	(20)	No.
Twelve,	(12)	Yes.
Ten,	(10)	Indefinite Reply.
Six,	(6)	No Reply.

I suspect the above data and other replies of my correspondents represent in a general way the present uncertainty in the country about the prevalence and characteristics of this disease. There seem, however, to be some facts that are quite patent. Yellow fever is said (1) by some to exist as a permanent endemic disease in some of our southern cities (New Orleans, *e. g.*, according to Chaillé); "with waves of increase and decrease down almost to no prevalence at all." Some equally eminent (Herrick), declare that it cannot be called endemic in New Orleans, and that it might be extirpated but for importation. From both of these parties we may infer that it virtually has a permanent habitation there. But for an accurate and minute knowledge of the essential cause of the disease and means for its prevention we must look to the coming century.

It seems (2) equally plain that during the last centennial period, yellow fever has virtually wholly disappeared from Boston, New York, and Philadelphia, in which latter city it prevailed to a terrible degree in the latter part of the last and in the earlier part of this century.

May we not hope that as in the past, so in the future, there may be a gradual pushing back of this frightful disease until it shall be fairly excluded from our borders!

(δ) *Has any law been passed relative to the prevention of the Cattle Disease?* The answers are:—

Twenty,	(20)	No.
Eleven,	(11)	Yes.
Five,	(5)	Indefinite Reply.
Twelve,	(12)	No Reply.

As at one time pleuropneumonia among cattle threatened very seriously to interfere with the food of the people, I deemed this a proper question. It is evident from my correspondence that it has influenced very differently the different States. In those States where it occurred, as *e. g.* in Massachusetts and in some of the Western States, much money was expended, large meetings were held, and many cattle were slaughtered in order to check it. I may refer on this subject to my correspondent of Illinois (Dr. Breed) for an interesting notice of what was done at a Convention of Cattle Dealers of the Northern States and Canada; to the Report of the Metropolitan Board of Health in New York, and also to

the action of the Massachusetts Legislature. By strict quarantine and care in sanitary matters connected with the cattle, and absolute destruction of those earliest seized with the disease, and above all by a national co-operative action rather than by that of any single State, I believe we may keep that and all such pests at bay. But eternal vigilance will be needed on all the great ways for cattle traffic, so that the disease shall not get a foothold in the country, otherwise disaster may follow. In connection with this subject I would refer to the report made by the United States Commissioner of Agriculture on the Diseases of Cattle, containing investigations by Prof. Gamgee, and by Drs. Billings and Woodward of the United States Army.

(j) *Has any law been passed regulating Tenement Houses for the poor?* The answers are:—

Thirty-three,	(33)	No.
Four,	(4)	Yes.
Three,	(3)	Indefinite Reply.
Eight,	(8)	No Reply.

That is, on this most important measure, on which so much depend the health and morality, and intellectual progress of a people, only four, ($\frac{1}{16}$) one-sixteenth of the various governments, have, according to my correspondents, done anything, while ($\frac{15}{16}$) fifteen-sixteenths either reply negatively or indefinitely, or not at all.

In the light of what is doing in England by public law, and in New York and Philadelphia by less comprehensive, but most opportune private work, on the basis of pecuniary gain, combined it may be with philanthropy, this report seems meagre. In this connection, I beg leave to refer to interesting correspondence with Drs. Harris and Thayer of New York, and Dr. Ford and Mr. Blodget of Pennsylvania.

(k) *Has any law been passed relative to incorporating Building Companies for the improvement of the dwellings of the poor?* The answers are:—

Twenty-nine,	(29)	No.
Six,	(6)	Yes.
Four,	(4)	Indefinite Reply.
Ten,	(10)	No Reply.

This question, allied to but more comprehensive than the preceding, has, as we see, received as little attention. Yet, strictly speaking, I know of no two questions more important at the present hour than this and the previous one. The fact is patent to every one that there are in every city and township in this land, and in every other country, dwelling places in which the poor are *obliged* to live, which are a disgrace to modern civilization. Such abodes are moral pests in the community, and sources of unmitigated evil to the Body Politic. They are, in fact, places in which it is impossible for the majority of human beings to grow up, except to filth, crime, and disease. These I fear will always exist, unless the public authority takes charge of these tenements and either builds others under State laws, or authorizes associations, partly for pecuniary and partly for philanthropic and sanitary reasons, to erect them. Having erected them it will be necessary to faithfully supervise them at all times and seasons, otherwise filth, and consequently disease, will come as heretofore.

We have one house in Boston yclept in derision the "Crystal Palace," which is occupied, when full, by about three hundred people, and which has been for years the abode of drunkenness and crime. It was well known to the officers of the State's Prison as its chief primary school of Crime. I know it well. It is impossible to tell at this time the rich

though painful experience gained from it by the Boston Co-operative Building Company. This, as its name partially indicates, was incorporated by the State in order to enable philanthropy and capital to unite on an equitable basis, viz., in newly building or in renovating the houses of the poor, with the hope of receiving an adequate return for the capital expended. This corporation has been a success in building many houses, united in a block, and giving a perfect home to every family, only one, or at the most two, families being on one floor. But desirous of trying the plans followed so successfully, by Mrs. Octavia Hill, of London, in her renovation of some of the most wretched houses in that Metropolis, the Boston Association took possession of this "Crystal Palace." We forthwith drove tenants from the filthy cellars and opened windows into every bed-room, the large majority of them having previously had none. We shut *two* of the *dark passages leading as common corridors to all the tenements* in the building, but we could not shut up a *third*. At first our success seemed very certain, but the commercial panic came in 1873, and that drove away many, and paralyzed the labors of others of the tenantry. Finally the lease was given up for this reason chiefly, that we were losing money. But even if it had been a pecuniary success, it became the decided opinion of most of the Committee, who had charge of it, that morally it must, from the inherent vices of its construction, *remain vile.*

Whilst so many are congregated in one house, with long dark common corridors actually inviting vice and crime of the lowest kinds, it is impossible to check the tendency thereto. The committee saw young girls and boys grow up into vice (without a possibility of saving them), owing, as it appeared in a great measure, to the very structure of the tenement, and of its out-buildings.

Whilst taking this opposition to the idea of large buildings, with dark, easily accessible, common corridors, instead of rows of moderate-sized buildings, containing but few families, it was gratifying to the committee to find that the death-rate in the building was much lessened by the alterations made in it, and by constant vigilance in regard to sanitary rules, as far as it was possible to have any rules, in a place provided with a few common privies and slop receptacles, which were constantly, day and night, resorted to by people having small ideas even of the comfort of cleanliness, and totally ignorant of its immense value in a hygienic point of view.

I have cited this case simply because of my four and half years of personal experience upon it. But the same facts of wretchedly constructed abodes for the poor exist everywhere, and human nature is the same. Our experiment, I think, proves very conclusively the folly of expecting people to be temperate, or honest, or healthy in badly constructed houses. I commend this topic of providing *suitable homes*, not houses only, for the people, as one of the most important that can command the attention of Philanthropy and Capital during the coming Century.

SEVENTH QUESTION.—(a) *Are there well-attested facts proving that any disease formerly prevalent in your State has ceased to appear?*

The answers are:—

Twenty-five,	(25)	No.
Nine,	(9)	Yes.
Eight,	(8)	Indefinite Reply.
Six,	(6)	No Reply.

Of the nine affirmative replies not one can present positive proof of the statement, but some suggest a lessening of some diseases. This seems to be undoubtedly the fact in regard to malarial fevers, yellow fever, etc.

That intermittents have disappeared from some localities, which have been drained, seems to be true. Smallpox is wonderfully lessened and quite shorn of its terrors. A few special diseases, as, for example, the "milk sickness," and the "black tongue," are mentioned as having prevailed formerly, but not of late. These statements, though less reliable than accurate statistic proofs, give us hopes for the future when State Preventive Medicine shall have obtained its due influence.

(b) *Are there any well-attested facts proving that any disease formerly prevalent in the State has been crushed by State or Individual action?* The answers are:—

Thirty-seven,	(37)	No.
None,	(0)	Yes.
Four,	(4)	Indefinite Reply.
Seven,	(7)	No Reply.

The returns give a most decided negative, and not a correspondent takes the affirmative of the question.

Eighth Question.—*Are there any similar facts proving that any special disease has arisen or been generated, or has been introduced into the State during the past century, which did not exist in Colonial Times, and which now remains endemic?*

The answers are:—

Twenty-seven,	(27)	No.
Six,	(6)	Yes.
Two,	(2)	Indefinite Reply.
Thirteen,	(13)	No Reply.

The same indefiniteness of statement prevails on this question as on the preceding. In one of the six affirmative replies, Dr. Denison, of Denver, claims that perhaps phthisis has been introduced into Colorado. Of course it has been, as a great many go there now as a place most fitted for the cure for the disease. And future statistical mortuary data, unless care be taken, will lead to great errors of judgment in regard to the value of that climate, and its influence on phthisis. In some of the Northern States some physicians claim that cerebro-spinal meningitis, diphtheria, and even croup, have been introduced during the centenary. There are grave doubts about the truth of all such statements. Others claim that yellow fever and cholera are such diseases; "yellow chills" are named by one, "trichiniasis" by another. I feel that there is no proof that any new disease has been introduced, and become endemic here.

Ninth Question.—*If there be any such new disease, has it been investigated by the State or by individuals?*

The answers are:—

Twenty-seven,	(27)	No.
Six,	(6)	Yes.
Two,	(2)	Indefinite Reply.
Thirteen,	(13)	No Reply.

My correspondents cite investigations by a commission of the city of New Orleans in 1853, relative to typhoid fever; by Dr. Kedzie, of

Michigan, on cerebro-spinal meningitis; on diphtheria, by the N. Y. Metropolitan Board of Health; on "yellow chills" by various persons in Alabama.

Of course this meagre statement falls far short of the truth in regard to the number of investigations undertaken by individuals, corporations, and commissioners, on the various diseases of the country, some of which have no more right to be classified as new diseases, than typhoid fever and diphtheria; and none of them can be certainly said to be diseases never seen before the past century.

TENTH QUESTION.—*Has the town or city in which you reside taken any measures for the improvement of the Public Health?*

(a) *By health laws?*

The answers are:—

Nine,	(9)	No.
Twenty-five,	(25)	Yes.
Nine,	(9)	Indefinite Reply.
Five,	(5)	No Reply.

From the above, it seems that the majority of the towns have done what mere self-defence would inculcate. But of the twenty-five affirmative replies very many report either inefficient enforcement or complete abeyance of such laws. Many towns have special laws for drainage, and other objects seem partially or wholly ignored. For my own State of Massachusetts, I think I can say that in not a single town has there ever been a complete system of health laws enacted and thoroughly enforced. But, notwithstanding this unsatisfactory statement, I also believe that I may with equal truth assert that so recently has the idea of State Preventive Medicine begun to take hold of our people, that our advance has been quite as much as could be expected. Very many more years will be needed before this country or Europe will even approximate to that point which, at present, only an ideal sanitary legislation would require, but which the coming century will bring forth into actual operation.

(b) *By special action in specific cases?*

Three,	(3)	No.
Twenty-five,	(25)	Yes.
Eleven,	(11)	Indefinite Reply.
Nine,	(9)	No Reply.

The remarks made on the previous question apply to this.

ELEVENTH QUESTION.—*Does your town use well-water for culinary uses?*

TWELFTH QUESTION.—*Is care taken to prevent pollution?*

THIRTEENTH QUESTION.—*Do you have a water supply from distant lake or river?*

FOURTEENTH QUESTION.—*Is care taken to prevent pollution?*

Including all these questions under one category; of 143 towns 82 use wells, 61 use rivers or lakes. In regard to the care taken to keep either class of waters pure, I find as follows:—

49 or 34.26 per cent. try to keep it pure;
69 or 48.25 per cent. make no attempt to do so;
25 or 17.48 per cent. make no, or an indefinite reply.

In other words, taking my returns as furnishing at least an approximation to the general state of the country in this respect, 34.26 per cent. only of the towns make any claims, even the most trivial, to be careful of the purity of their water; while 65.73 per cent., or nearly twice as

many, are totally neglectful. That is to say, nearly two-thirds of the people of this Union are living in a senseless disregard as to whether they are drinking pure water or water which, though "sparkling and tasting pleasant," may be loaded with every species of filth!

FIFTEENTH QUESTION.—*Have you sewers to carry off such water supply?* The answers are:—

Eleven,	(11)	No.
Thirteen,	(13)	Yes.
Twenty,	(20)	Indefinite Reply.
Four,	(4)	No Reply.

These replies coincide with all the preceding, and intimate very fully the primitive ideas held by the people of this country in regard to the necessity of carrying off water once made impure. What happens in Boston I fear happens elsewhere, viz.: that abundant supplies of water have been introduced into certain parts of the city without any immediate provision being made for its removal by sewers. The consequence has been that the cesspools have been overflowed, and that the land has been soaked with water, perchance containing the elements of disease, and certainly tending to develop phthisis, from the soil moisture induced by such overflow. Of course, evil must result.

I might refer to other particular cities and places, now the common summer resorts for the most wealthy people, where a most scandalous condition exists in this respect, making it at times more dangerous to visit the "health resort," so called, in country and sea-side, than it would be to remain at home, even in a poorly-sewered, offensive-smelling city. But we have no need to visit health resorts to find great imperfections of sewerage. That of Boston, which I have already quoted in reference to its suburbs, has been, even within its city limits, notoriously bad, notwithstanding it has been claimed to be nearly as perfect as could be. Some of the main sewers of that city are even now nearly filled with refuse, more or less solid. One of the main conduits is occupied to a great depth by so-called "mud," composed of dirt from the open street gutters and of human excreta. Others are more or less partially obstructed. The whole congeries of them form one vast network of cesspools, belching out at times filthy odors from "manholes" along the streets. The mouths of the sewers, which open all around the city limits, and in the closest proximity to it, pour forth volumes of similar foul exhalations while the tide is low, and the quantity of refuse issuing from them has been declared, under oath, to interfere very much in certain places with trade, by preventing vessels which were formerly able to approach certain wharves, from so doing at the present time.[1] I summon thus significantly my own city to the bar of public sanitary rebuke, not because I think her really a worse sinner in these respects than many other and some greater cities, but for two reasons: (1) that I know whereof I speak, and can vouch for the truth of the assertions, extraordinary as they may seem to some of you, and (2) that I rejoice to say that, in this centennial year, Boston is seemingly repentant, and is prepared to amend her system at a large expense. Thank God! Her citizens are beginning to feel that the *worst prodigality is the waste of human life*, and that *mere money is as nothing before the idea of perfect human health!*

[1] *Vide* Tyler et al. *v.* Squire et al., before the State Board of Health of Massachusetts, 1873.

SIXTEENTH QUESTION.—*How far are the sewer outlets from the source of water supply?*

Upon this question it may be generally stated that these distances in different cities of the Union vary from what may be practically called zero to 20 or even 30 miles. It would seem that, where it is convenient so to do, a distance more or less great is always chosen; but strange as it may seem, some of our great cities have been wholly thoughtless. If my correspondent be correct, even in this great city of Philadelphia in which we meet, although the majority of the sewerage is carried far below the water supply, we cannot claim the same for all of it. And not a few cities which take water from rivers and lakes are practically regardless of the quantity of impurities that enter the stream or lake at some distance, it may be, but nevertheless *above* the part whence the city gets its own water supply. I might cite Albany as a great and most glaring example of this latter statement.

SEVENTEENTH QUESTION.—*What is your method of disposing of sewerage? House offal? Slops or filth liable to accumulate about homesteads?*

I have received answers from eighty-four towns, and the summary of them is, that only in about one-fifth (sixteen) are there any proper and efficient means for the removal of these various sources of contamination. A great many have still most primitive ways of disposing of them; "they are thrown away carelessly." Many have "surface drainage." In some they are "thrown into open lots," or "to the hogs;" and in some "each inhabitant does as his own will dictates." Nothing can be more chaotic than the present method pursued in this country, considered as one great whole.

EIGHTEENTH QUESTION.—*Have any State, County, or City reports of Health or Deaths been published?*

The answers are:—

Thirty,	(30)	No.
Nine,	(9)	Yes.
Two,	(2)	Indefinite Reply.
Seven,	(7)	No Reply.

That is, 62.50 per cent., or more than half of the correspondents, say there is no registration in their States; 18.75 per cent. have had some registration, most of them only for a few years past; and 18.75 per cent. make indefinite or negative replies. Adding together the first and last items as being essentially the same, we have, as the final probable result, that 81.25 per cent., or more than three-fourths of these States, have virtually ignored vital statistics during the whole centennial period. Add to this that among those which claim to have had registration, it is likewise stated by my correspondents that in not a few the registration is very imperfect.

The United States commenced its national censuses in 1790, and has continued them decennially ever since, but never with the accuracy which is desirable. I judge this from the opinion of experts whose opinion I have asked of even the latest, that of 1870. The following remarks by General Walker and Mr. Elliot seem also to indicate that my inference is true.

General Walker says: "The gross incompleteness of the returns of deaths in the census of the United States is shown by Mr. Elliott's Approximate Life Table. What, it may be asked, is the value of statistics

confessedly so imperfect?"[1] He elsewhere admits that the number of deaths falls short 40 per cent. of what must actually be the fact.

Mr. Elliot, who calculates life tables from these returns, admits that he is obliged to "resort to the somewhat arbitrary assumption of 40 per cent. limited, however, by an investigation of the rates of mortality relative to population which obtain in other communities, so far as accessible, and in portions of our own country."[2]

NINETEENTH QUESTION.—*How many years, approximately or definitely, have these registration reports been published?*

I regret that, owing to imperfect returns, I cannot give any but general statements.

But when I think of the comparatively brief period of time since the registration has been commenced in the different States where any is made, and knowing as I do, the imperfections of those which may be supposed to be the best, I feel sure I am within the limits of truth, when declaring that not a State in this Union has a registration which has been in progress a sufficient number of years, or which has been conducted with sufficient accuracy, to be fairly comparable with that registration which will be eventually demanded by an enlightened State Preventive Medicine, after that idea has been firmly grasped and acted upon for some years by the intellect and conscience of our people.

In confirmation of this assertion, I state the following fact. I was desirous of learning definitely, not from theorizing on the influence of civilization, not from the records of foreign countries, but from accessible statistics collected and printed in this country, whether man lives longer now than at the commencement of the centennial period. I consulted several eminent American experts in statistical data. I asked them to point out to me any such data. Not one of them could do so. One who stands pre-eminent, and whose word is listened to by Europe, advised me as follows: "You may consult bills of mortality; grave-yard records; family Bibles; traditions of the former and later times, and they will show whether we have gained or lost in longevity." I have no doubt that, provided we could find those records, we should perhaps partially gain the end proposed. My question was whether he could point out to me any printed document, derived from accurate records made in the United States, answering my question. He could not do so.

TWENTIETH QUESTION.—*Has any law of development, or of partial development, of any disease been discovered by individual or State action, by attention to which in coming centuries we may hope to greatly lessen or destroy such disease?*

I proposed this question of fact as the test question, so to speak, of the Centennial Period. It was the culmination of all these questions hitherto proposed.

The answers are:—

Thirty-nine,	(39)	No.
Six,	(6)	Yes.
None,	(0)	Indefinite Reply.
Three,	(3)	No Reply.

The returns indicate that my correspondents have a more decided opinion upon this question than upon any other of the series. There are

[1] Statistical Atlas of the United States. By F. A. Walker.
[2] Ibid. Approximate Life Table for the United States. By E. B. Elliott.

only three who fail to make any answer, and not a single State has replied indefinitely. Again, thirty-nine out of forty-eight States, or 81.25 per cent., reply in the negative; six of the forty-eight, or 12.50 per cent., reply affirmatively.

But let us look carefully at the affirmative replies, and interpret more closely their exact meaning. The replies I think may be justly arranged in two categories:—

First. Those in which it appears that by close attention to sanitary arrangements, and their rigid enforcement, certain diseases are checked. One correspondent remarks, "all the acquired knowledge concerning all and each of the typho-contagia, and the factors of their propagation is equivalent to discovery." (Dr. Harris, of New York.) From other States we are informed that "the laws of development of typhoid fever are known better." (Drs. Plummer, of Oregon, and Butler, of Vermont.) Drs. Stuart and Toner, of Washington, D. C., say they are "able to control and prevent zymotics by sanitary enforcement." Dr. Baker, of Lansing, the self-sacrificing, efficient Secretary of the State Board of Health of Michigan, writes as follows: "It seems proper to modify very much the 'Yes,' which I have placed opposite the question; if we substitute for 'law of development,' or 'partial development of,' the words 'general truth respecting,' I think the answer will be truthfully 'Yes.'" He then cites scarlet fever "which will be lessened in the near future, because of the accumulated evidence of the great mortality caused by it." He also thinks "croup and pneumonia will be eventually greatly lessened from the fact that a cold and dry atmosphere causes the greatest mortality from both. And by securing such favorable conditions in our houses, and particularly in our sleeping rooms, it is reasonable he thinks, to hope that many deaths from pneumonia and croup may in the future be prevented." These may be considered as one category.

Second. Let us grant that all this is true, nevertheless I do not see that any "law" of development of disease, similar in degree at least, if in character, to that of "soil moisture" as a very prominent cause of phthisis, has been presented by any of the above respected correspondents. Massachusetts, through the agency of the Massachusetts Medical Society,[1] proved many years ago by data received from her three hundred and twenty-five towns, and where consumption had been previously considered everywhere equally endemic, that there were dry spots where it was very rare, and wet where it was very rife. By accurate statistical data, laboriously gathered, it was further proved that of two families growing up, one on a wet soil and the other on a dry soil, the one resident on the wet by that fact became twice, if not three times, as liable to phthisis as the other, resident on a dry spot. That law was first discovered and announced in New England, and subsequently by ample statistical data proved to exist in Old England. I think it may now be said to be a Cosmic Law, and as such it seems to me I am justified in placing it alone in the second category under this final question.

In order to meet the numerous similar questions which will inevitably arise in the future, we need, as Mr. Elliot suggests, a National System for the registration of all the Births, Marriages, and Deaths taking place in the country. Moreover, the Registrar should, for the whole country, learn the exact character of the localities in which the deaths take place, if we would know exactly and broadly the endemic influences of any place.

[1] Topographical Distribution of Consumption. Annual Address before Mass. Med. Society, 1867.

SUMMARY.

Gentlemen: My work is done. I have endeavored to place before you the exact truth in these matters so far as I could obtain it. No one can feel more keenly than I do that it has at times been most unpalatable, and that it seems to be but little creditable to the country. Nevertheless, looking at the very recent growth of a regard for Public Hygiene, and at the certain though small advances made in various parts of the country in State Preventive Medicine, I have the strongest hopes for the future of our Country and the world in this regard. We could not, with the influences hitherto pressing upon us, have advanced further. System making, the outgrowth of many previous centuries, prevented all progress in this direction during our first epoch. The overthrow of these theories and theory makers, and the bringing of medical inquiries into line with the methods pursued by modern science, was the great fact gained during the second. Although this has been followed by a sweeping and widespread skepticism in our own art, we must remember that this same skepticism is found everywhere within the domains of modern thought. Good will ultimately result from it. But these facts have not allowed of the growth of Preventive Medicine until within a very recent period of time.

We stand now at the very dawn of the grandest epoch yet seen in the history of medicine. While philosophically, accurately, and with the most minute skill, studying by means of physiology, pathological anatomy, chemistry, the microscope, and, above all, by careful clinical observation, the natural history of disease and the effects of remedies, our art, at the present time, looks still higher, viz.: to the *prevention of* as well as to the *cure of* disease. And this is to be done by sanitary organizations throughout each State and the Nation, the laity and the profession heartily joining hands in this most noble cause.

Our Present Duty.

Our present duty is organization, National, State, Municipal, and Village. From the highest place in the National Council down to the smallest village Board of Health, we need organization. With these organizations we can study and often prevent disease.

This great and beneficent object of the prevention of disease appeals to all. The aged may give counsel. To the young of this and of future generations belongs the solid work which is to bless the coming centuries. I appeal therefore with all the earnestness at my command to the young men of the present hour. Can there be anything more inspiring to a generous hearted, intelligent youth than the thought that, by laborious research into the causes of disease, by the discovery of means for its prevention, and by the teaching of these various causes and means to the people, he may help to save even a few of the more than two hundred thousand human beings now annually slaughtered in this country by preventable disease?

Our Hopes for the Future.

I trust that this discussion will have given rise in your minds to some of the bright hopes for the future which have arisen in my own. Although Public Hygiene has made but few advances hitherto, it is nevertheless founded upon Natural law. It has been legitimately and healthfully growing during a portion of the past quarter of a century. Modern Science greets it and brings it within its domain as one of its most precious objects for thorough investigation. I hope therefore that, standing as we now are near to the close of this fair Centennial Birth-year of our Nation, up to whose festival all nations of the earth have been invited, I may be allowed to appeal to all, whether young or old, American or collaborating friends from other lands, to join with me in a *Cordial All Hail to Coming Centuries*, not only in America but in every civilized spot of God's earth; because everywhere, and to all coming time, human life will be lengthened, made more healthy, and consequently more truly happy, by the potent influence of

State Preventive Medicine.

ADDRESS ON MEDICAL CHEMISTRY AND TOXICOLOGY.

BY

THEO. G. WORMLEY, M.D., PhD., LL.D.,

PROFESSOR OF CHEMISTRY AND TOXICOLOGY IN STARLING MEDICAL COLLEGE, COLUMBUS, OHIO.

When it is remembered that nearly all human thought and labor are devoted to the promotion of the welfare of the human body, and that agriculture, manufactures, and commerce have this as their chief end, it will not be deemed strange that a science so comprehensive and withal so flexible in its applications as Chemistry, should be laid under contribution to preserve that body in health, or to restore that health when impaired. Before chemistry had become a true science, its aid was invoked by the old alchemists in their search for the "Elixir of Life." A universal remedy was the dream of many a toiler in secret places, whose occult science had for him a strange fascination. There were among the Arabians many who, in their rude way, applied such chemical knowledge as they possessed to the discovery of new medicines. The same was true of the earlier physicians of Europe. There was everywhere an effort to make nature reveal some secret which might be turned to account in the healing art. This, more than any other, was deemed the true function of Chemistry.

It was not until Bacon announced the true method of scientific investigation, and declared that the Kingdom of Science, like the Kingdom of Heaven, was to be entered as a child, rather than with the spirit of a dictator, that the mists of earlier times were gradually swept away, and the path prepared for the appearance of Science with exact methods and with exact results.

It is now only about a century since Chemistry took shape as a Science. The labors of Black, Priestley, Scheele, Lavoisier, and others showed that a vast field of research lay before them. For a century chemists have been exploring this field, and have taken possession of many a spot, and secured permanent title-deeds for posterity; but, it must be confessed, that a century is far too short for the survey of the whole domain, and our descendants will have ample scope and incentive for the profoundest labor and research. Only two years since, the chemists of Great Britain and America celebrated the centennial of Chemistry, dating the birth of the science from the discovery of Oxygen by the distinguished Priestley, August 1, 1774. The commemoration in this country took place at Northumberland, Pa., the American home of Dr. Priestley. The general progress of the century was there ably set forth by men of note in their several departments of investigation. The very valuable address of Prof. Benjamin Silliman, on this occasion, on *American Contributions to Chemistry* (a complete compendium to which we are greatly indebted) shows that in this country we have not been idle in advancing this department of science.

After the discovery of oxygen, nitrous oxide, and other gases, by

Priestley and others, Sir Humphry Davy, then a young man with majority unreached, was employed at Bristol, through the generosity of Messrs. Watt and Wedgwood, to undertake a careful series of experiments with gases as remedial agents. So important and intimate is the connection between chemistry and medicine, that we should naturally look to those who feel the imperative need of this science in its sanitary applications, for the best labors in the science. There could be no other incentive more potent. The air and vapors we breathe, the food we eat, the fluids we drink, the medicines we take, and the poisons we seek to avoid, all come within the range of the analyst, and his words of counsel and caution are to be heeded. In this field of labor many eminent chemists have labored with exclusive devotion, while others, as Davy, Scheele, and Liebig, commenced their distinguished careers as pharmacists, and may be said to have emerged from the apothecary's shop. Indeed, we may not overlook the close connection between chemistry and pharmacy. As we trace the history of medical chemistry in the United States, it will be seen that the contributions of the pharmacists have been so many and various, that the historian must give them a high and honorable place in the annals of American progress.

One hundred years ago we find that the only medical college in the land, with an occupied chair of chemistry, was the Philadelphia Medical College, soon after (1791) merged into the University of Pennsylvania, the institution in whose halls we are now assembled, an institution not only venerable in years, but renowned for the great and noble work it has accomplished. The occupant of this chair, elected August 1, 1769, was none other than Dr. Benjamin Rush, distinguished alike for his professional labors, which brought honor upon medical science, and for his devoted patriotism in the dark days when our national independence was won. He graduated at Princeton, and afterwards studied medicine in Philadelphia, Edinburgh, London, and Paris. While in Edinburgh he studied chemistry with the eminent Dr. Joseph Black. He was one of the signers of the Declaration of Independence, which this centennial year commemorates. In 1777 he was made surgeon-general of the army in the middle department. Ever a distinguished physician and medical professor, ever active in all public and philanthropic movements, his long life was one of singular usefulness and honor, and no name in our annals should be mentioned with more reverence and respect than that of Benjamin Rush, the earliest American professor of chemistry. The only other chair of chemistry in the colonial days was that established in William and Mary College, Virginia, in 1774, and filled by the Rev. James Madison.

In 1779 a professorship of chemistry and natural philosophy was established in the literary department of the University of Pennsylvania. Thus two of the first three chemical professorships in America were established in Philadelphia. In the medical department of Harvard University, Aaron Dexter was elected Professor of Chemistry and Materia Medica in 1783; and in 1792 Dr. Samuel Latham Mitchell was elected Professor of Chemistry in Columbia College, New York. Dr. Mitchell graduated in medicine in Edinburgh in 1786. Two years after entering upon his professorship of Chemistry, he published an essay on the *Nomenclature of the New Chemistry*. In 1797 he, with others, established the *Medical Repository*, the first scientific periodical ever published in the United States. He is now widely known as an early student of

natural history, and his publications on zoological subjects are yet prized.

In 1795 Professor John McLean, a young chemist of Scotland, was elected Professor of Chemistry in Nassau Hall, Princeton. In 1803 Professor Benjamin Silliman, the first professor of chemistry in Yale College, entered upon his duties. He became widely known as an able and eloquent expounder of chemical science. In 1818 he established *The American Journal of Science and Arts*, which became, more than any American journal, the means of disseminating discoveries in chemistry and in cognate sciences. His name will ever remain an honored one in the history of American science.

The work done in chemistry in the medical schools has not always been marked by scientific thoroughness; indeed, in too many cases, very little practical benefit has resulted from the lectures, often only heard to be forgotten. But a change is now being effected in this respect, and we note with satisfaction that a two years' course of systematic laboratory practice is made part of the regular curriculum of study in the Medical Department of Harvard University.

The earlier professors of chemistry in the Medical Schools did not contribute largely to the advancement of the science in the way of original research. The science was in its infancy, and the circumstances surrounding them were not generally such as to awaken that measure of enthusiasm which is necessary to scientific discoveries. A marked exception, however, is found in the case of Dr. Robert Hare, who became Professor of Chemistry in the University of Pennsylvania in 1818. In his youth he was a member of the Chemical Society of Philadelphia, to which belonged Priestley, Seybert, and others. At the early age of twenty, he announced the discovery of the oxy-hydrogen blowpipe, which at once gave him distinction in both hemispheres. This became a valuable instrument in certain departments of chemical investigations, and in the arts. Dr. Hare had great mechanical skill, and with his ingenious apparatus was enabled to perform experiments with great brilliancy and success. In addition to many valuable contributions, he published, in 1828, a *Compendium of Chemistry*, a valuable and useful work at the time. In this connection it should be mentioned that in 1819 Dr. John Gorham, Professor of Chemistry in the Medical Department of Harvard University, published the first original systematic treatise on chemistry ever issued in this country, entitled the *Elements of Chemical Science*, a work in two volumes, which reflected great credit upon its author. It should be stated, however, that there had been, before this, American republications of foreign chemical works.

We now come, in the order of history, to the name of Prof. John Redman Coxe, who deserves mention for the part he played in inaugurating a movement, which, as we shall see, has contributed, perhaps, more than any other to the progress of Medical Chemistry in the United States. A part of his medical education was obtained in the University of Edinburgh, but he graduated in the University of Pennsylvania in 1794. He afterwards spent considerable time in London, Edinburgh, and Paris. In 1809, he was elected by his Alma Mater Professor of Chemistry, and was transferred to the chair of Materia Medica in 1818. While in this latter chair he was the "leading spirit" in a movement to provide a special course of lectures in Pharmacy for the young druggists and druggists' clerks of Philadelphia. This was early in 1821. This movement arrested the attention of the leading druggists of the city, and led

them at once to establish a new and independent institution—first called the College of Apothecaries, but changed the next year to the Philadelphia College of Pharmacy—to secure the same results, but upon a more liberal plan.

The founders of this college were wise men, and secured for their new institution professors of high scientific character. The first course of lectures was given in 1821–2. Dr. Samuel Jackson, a medical graduate of the University of Pennsylvania, was the first Professor of Materia Medica. In 1827 he was elected to a professorship in his Alma Mater. His career as a lecturer, as an author, and as a practitioner, was in all respects distinguished. Dr. Gerard Troost, afterwards eminent in other departments of science, was the first Professor of Chemistry, but was succeeded within a year by Dr. George B. Wood, happily still living to enjoy the rewards of a life well spent in the service of science and of humanity. His published works, at once so complete and scholarly, have honored the profession of which he has so long been a distinguished member.

In 1831, Dr. Wood was transferred to the department of Materia Medica. His successor in the chair of Chemistry was Dr. Franklin Bache, a worthy descendant of the eminent statesman and philosopher whose name he bore. In 1833, Professors Wood and Bache published the first edition of the *United States Dispensatory*, a work which has passed through thirteen (13) editions, and is still the indispensable handbook of the physician and pharmacist. These eminent professors impressed upon the College of Pharmacy a character for thorough science which it has never lost. Our brief sketch would be imperfect should we here fail to mention the name of the late Prof. William Procter, Jr., who became the Professor of Pharmacy in this college in 1846, and who by his scientific labors, prosecuted through many years, contributed more to the special department of Medical and Pharmaceutical Chemistry than, perhaps, any other American. It should here be mentioned that, four years after the establishment of the Philadelphia College of Pharmacy, its friends founded the *American Journal of Pharmacy*, a journal still issued, and which has contributed very greatly to the dissemination of a knowledge of chemistry in its relations to medicine.

The second College of Pharmacy in this country was established in New York in 1829, through the instrumentality of George D. Coggeshall, a graduate of the Philadelphia College. The first Professor of Chemistry was the late Dr. John Torrey, whose labors in science, and especially in American botany, have given him a name which will ever be honored.

MEDICAL CHEMISTRY.

Having thus glanced at the history of the introduction of chemistry into our schools, in passing on to discuss the theme assigned us, MEDICAL CHEMISTRY, we find ourselves entering upon a broad domain of investigation. We might enlarge upon the many and wide bearings of chemistry upon medical practice, and show how indispensable it is to the best success of the practitioner; point out its grand achievements in the departments of physiology and pathology, and show how inseparable is its connection with the progress of medical science in all its departments;

but, perhaps, as more consonant with the occasion and with the limitations of the hour, we may restrict ourselves to a brief consideration of the more prominent of the *American Chemical Contributions to the Medical Progress of the Century.* In this review, we find that these contributions relate largely to the examination of the chemical and therapeutic properties of our indigenous plants.

One of the first of these plants examined was *Sanguinaria Canadensis*, or Blood-root. Attention was first called to this plant in 1803, by Dr. Wm. Downey, of Maryland, as a powerful emetic; and in 1819, Dr. Wm. Tully, of New Haven, investigated with care its therapeutic properties. In 1828, Dr. J. F. Dana, of Dartmouth, first chemically examined the plant, and succeeded in isolating a basic or alkaloidal principle which he called *Sanguinarine* (N.Y. Lyc. Nat. Hist., ii. 245, 1828). The identity in ultimate composition of this alkaloid with the alkaloid of *Chelidonium majus*, subsequently discovered by Probst and called *chelerythine*, was fully established by Dr. Joseph Schiel, of St. Louis, in 1865 (Amer. Journ. Sci. (2), xx. 220). A second principle was extracted from Sanguinaria Canadensis by Riegel, which he considered identical with Merck's porphyroxine, from opium; but this identity was subsequently denied by Dr. G. D. Gibb. A third proximate principle derived from this plant was described by Prof. E. S. Wayne, of Cincinnati (Amer. Journ. Pharm., 1856, 521); and for it Dr. Gibb proposed the name *puccine.* Prof. Wayne has also recognized in blood-root the presence of *chelidonic acid*, first found in the plant Chelidonium majus.

In 1819, Dr. John Torrey, while investigating a curious underground fungus called Tuckahoe or Indian-bread (*Scleroticum gigantium*), discovered a new principle which he termed *Sclerotine*, an account of which was read before the Lyceum of Natural History, New York, Nov. 15, 1819, and published in the N. Y. Med. Repository, Dec. 1820. In 1824 Braconnot described pectic acid, a principle now obtained from many succulent plants. In 1827 Dr. Torrey republished his former paper with additions, and showed the identity of the two substances (Amer. Journ. Sci. (2), xxvii. 439).

Another interesting native plant that early received attention is *Lobelia inflata*, known as Indian tobacco, and used as a medicine by the aborigines. The attention of the medical profession was first called to this plant by Rev. Manasseh Cutler, of Ipswich, Mass., eminent as a botanist in the latter part of the last century. Lobelia was first examined chemically in 1833 by Dr. S. Colhoun, Professor of Materia Medica in Jefferson Medical College, Philadelphia, who announced the existence of a basic principle capable of forming salts with acids, but failed to isolate the principle (Amer. Journ. Pharm., v. 300, 1833). Wm. Procter, Jr., who has already been referred to, in his Inaugural Thesis, in 1837, on Lobelia inflata, demonstrated that the active principle of the plant is a liquid alkaloid, which he succeeded in isolating. He named this principle *lobalina*, and he described the salt formed by it with the leading acids. His very elaborate thesis was published in the American Journal of Pharmacy for July, 1837. In November, 1850, Wm. Bastick read a paper before the Pharmaceutical Society of Great Britain on Lobelia inflata, in which he described the same alkaloid, and his name is often mentioned in foreign publications as its first discoverer. A number of cases of poisoning have occurred in this country from the use of this plant, chiefly as administered by empirics.

The next indigenous plant to be noticed is *Veratrum viride*, or Ameri-

can hellebore. This plant was known to the Indians chiefly as a poison. According to Joselin, an early visitor to this country, it was used by them in the selection of their chiefs, the individual found least susceptible to its effects being regarded as the "strongest of the party, and entitled to command the rest" (Amer. Journ. Pharm., vii. 203). It was brought to the attention of the medical profession about the year 1830, by Drs. Tully and Ives, of New Haven. Its therapeutic properties were more fully investigated by Dr. Charles Osgood, of Providence, in 1835 (Amer. Journ. Med. Sci., xvi. 296). In 1851 Dr. W. C. Norwood, of South Carolina, again brought it before the profession in a series of papers highly extolling its medicinal virtues.

The chemical history of this plant presents some features of peculiar interest. Very contradictory conclusions have been reached by different investigators in regard to the exact chemical nature of its active principle or principles. The first chemical examination of this plant was made in 1835 by Dr. Charles Osgood, but he failed to obtain satisfactory results (Amer. Journ. Pharm., vii. 202). It was again examined by Dr. Thos. R. Mitchell in 1837, who also failed to determine the true nature of its active principle (Ibid., ix. 181). After a somewhat extended examination, Henry W. Worthington, in 1838, concluded that the plant contained an alkaloid identical with *veratria*, previously obtained from veratrum album, its European congener (Ibid., x. 89). In 1857, Dr. Jos. G. Richardson, after a very elaborate investigation and an extended series of parallel chemical experiments, with the alkaloids of both these plants, came to the same conclusion (Ibid., 1857, 204). In 1862 Mr. G. J. Scattergood announced that in addition to the alkaloid *veratria*, the plant contained a resin, to which he ascribed the sedative action of the drug, and he also obtained some evidence of the probable existence of the alkaloid *jervia* in the plant (Proc. Amer. Pharm. Assoc., 1862). Mr. Charles Bullock, of Philadelphia, in 1865, claimed that the alkaloid in question was not identical with *veratria*, and that the resin of Scattergood owed its activity to the presence of another alkaloid. These principles were afterwards named respectively *veratroida* and *viridia* (Amer. Journ. Pharm., 1865, 321). In 1872 Dr. Eugene Peugnet, of New York, also assented to the want of identity between veratroida and veratria, and he announced the identity of the viridia of Bullock with the alkaloid jervia, first discovered in veratrum album by Simon (Med. Record, May, 1872). These views of Dr. Peugnet were endorsed by Mr. C. L. Mitchell, of Philadelphia, after an elaborate investigation in 1874 (Proc. Amer. Pharm. Assoc., 1874, 436). Lastly, in this singular history, in a paper in the January number of the American Journal of Pharmacy for the current year, it is again claimed that the alkaloid, other than jervia, of this plant *is* identical with veratria, it fully responding to all the known tests for this alkaloid. The paper just cited, by Dr. T. G. Wormley, also points out the behavior of jervia with reagents, and cites cases in which both alkaloids were recovered from the blood of animals poisoned with veratrum viride.

In 1875 Mr. Charles Bullock contributed a valuable paper on the methods of preparation and properties of jervia (Amer. Journ. Pharm., 1875, 449). In this connection we should not fail to mention the interesting and valuable series of experiments upon the physiological action of the alkaloids of this plant by Prof. Horatio C. Wood, Jr., of Philadelphia, published in the American Journal of the Medical Sciences, January, 1870, and the Philadelphia Medical Times, vols. ii. and iii.

Leaving this protracted notice of the American hellebore, let us turn to a plant of milder name and properties, the Wax Myrtle or Bayberry, the *Myrica cerifera* of the botanists. In 1819 the berries of this plant were examined chemically by Dr. J. F. Dana, then chemical assistant in Harvard University (Amer. Journ. Sci., i. 294). Mr. G. E. Moore, in 1862, made a complete analysis of the Wax of the Bayberry, and found it to consist of *palmitin* and *palmitic acid*, with a small quantity of *lauric acid* (Ibid. (2), xxxiii. 313). In 1863 the bark of the root of this plant was examined by Mr. Geo. M. Hambright, of Philadelphia, who found that it contained a new crystallizable principle, to which he gave the name *myricinic* acid (Amer. Journ. Pharm., 1863, 193). The bark of this plant, as a remedial agent, was first brought to the attention of the profession in 1822, by Dr. W. M. Fahnestock, of Harrisburg, Penn.

According to Rev. F. Heckewelder, the Indians of this country employed *Podophyllum peltatum*, or May apple, as a poison to destroy themselves (Eberle's Therapeutics, i. 205). This plant was long used as a popular cathartic, and was brought to the attention of physicians, by Dr. Bigelow, about 1818.

The first chemical examination of this plant was made in 1831, by Wm. Hodgson, who obtained a crystallizable bitter principle, which he believed to be the active principle of the plant, and which he named *podophyllin* (Amer. Journ. Pharm., iii. 273); but Prof. T. F. Mayer was led to believe that the principle obtained by Hodgson was the alkaloid *berberina* (Ibid., 1863, 98); and this fact was fully established by Prof. J. M. Maisch (Ibid., 303). After an elaborate examination of the plant by John R. Lewis, the results of which he presented as an Inaugural Essay, he concludes that the active properties of the root are due to the presence of two peculiar resinous principles, the one soluble, the other insoluble, in ether (Ibid., 1847, 165). According to Prof. Mayer, the root contains, besides berberina, a colorless alkaloid, a neutral volatilizable principle, and saponine (Ibid., 1863, 98).

A native plant that has received considerable attention at the hands of the physician and chemist is *Hydrastis Canadensis*, or Yellow puccoon. It was known both as a medicine and as a dye to the aborigines of this country, and employed by irregular practitioners before being used by the regular profession. The first chemical examination of this plant was made in 1851, by Alfred A. B. Durand, of Philadelphia (Am. Journ. Phar., 1851, 112). He obtained a colorless crystallizable base, which he named *hydrastia*, but he failed to obtain it in a pure state. In 1862, Mr. J. D. Perrins, of Worcester, England, obtained it pure and determined some of its properties. He read his paper before the London Pharmaceutical Society, April 2, 1862, an abstract appearing in the Chemical News (v. 204), and the paper in full in the London Pharmaceutical Journal for May, 1862. In 1863, F. Mahla, of Chicago, Illinois, in a very valuable paper published in Silliman's Journal (op. cit. (2), xxxvi. 57) very fully describes the properties of hydrastia and gives its ultimate composition. We have given the history of this alkaloid somewhat in detail, since there have been different claimants for the honor of its discovery.

Mr. F. Mahla, in 1861, fully established the presence of *berberina* in the hydrastis Canadensis (Sill. Journ. (2), xxxiii. 43). This was the first instance in which this alkaloid—now known to be so widely distributed in plants—was found in a plant belonging to the Ranunculaceæ, and it thus established the fact that the same alkaloid may occur in plants belonging to different families. The chemical history of the alkaloid

berberina is somewhat remarkable. In 1826, Chevallier and Pelletan discovered it in the bark of *Xanthoxylum clava Herculis*, and named it *xanthopicrite.* In 1835, it was found as *berberina*, by Buchner, in *Berberis vulgaris.* These observers erroneously regarded it as a weak acid. Fleitman established its basic character; and Perrins, in 1862, showed the identity of xànthopicrite with berberina, and established its formula. The probable existence of a third alkaloid in hydrastis canadensis, "more resembling berberina than hydrastia, but decidedly different from the former," was announced in 1873, by A. K. Hall, of Ann Arbor, Mich. (Am. Journ. Phar., 1873, 247). This third principle was more fully examined in 1875, by John C. Burt, of the University of Michigan (Ibid., 1875, 481).

Cimicifuga racemosa, or Black snakeroot, a native of the United States, was first introduced to the attention of the regular profession by Dr. Thos. J. Garden, of Charlotte, Va., in 1823. This plant was examined chemically in 1834, by John H. Tilghman (Amer. Journ. Phar., vi. 14); in 1843, by J. S. Jones (Ibid., xv. 1); and in 1861, by Geo. H. Davis (Ibid., 1861, 391); but neither of these gentlemen succeeded in obtaining the active principle of the plant. At a meeting of the N. Y. Academy of Medicine, April 3, 1871, Dr. S. R. Percy exhibited a sample of a new alkaloid obtained by him from the cimicifuga racemosa, which he named *cimicifugia* (Amer. Med. Times, N. Y., April, 1861).

The poisonous nature of the leaves of *Prunus Virginiana*, or Wild cherry, has long beeń known. As early as 1806, Dr. Coxe, of Philadelphia, conjectured that the poisonous properties of water distilled from the leaves of this plant were due to the presence of prussic acid (see Am. Journ. Pharm., 1859, 433). In 1834, Stephen Procter determined the proximate composition of the bark of the tree, and established the presence of hydrocyanic acid and a volatile oil, as products of distillation with water (Amer. Journ. Pharm., vi. 8). In 1838, Prof. Wm. Procter, Jr., established the existence of *amygdaline* and of a decomposing agent, identical with *emulsine*, in the bark, leaves, and kernels of the wild cherry, and showed that these principles (as had before been shown by Liebig and Woehler in the case of bitter almonds) were the source of the volatile oil and hydrocyanic acid obtained by distillation (Ibid., x. 197).

In 1856, Prof. E. S. Wayne, of Cincinnati, obtained from the root of *Leptandra Virginica*, or Black root, a peculiar, bitter, crystallizable principle, which possessed the properties of the plant, and which has been named *Leptandria* (Amer. Journ. Pharm., 1856, 510). Prof. Wayne also found that the root contained mannite (Ibid., 1859, 557). In 1863, Prof. F. F. Mayer announced the presence in the plant, of a glucoside closely resembling senegin in its properties, but more readily decomposed by alkalies (Ibid., 1863, 298).

We may next notice *Rhus toxicodendron*, or Poison oak, a native plant well known from its peculiar action upon the skin of some individuals. It was used by the Indians, both as a poison and as a medicinal agent. The first chemical examination of this plant seems to have been made in 1857, by Dr. Joseph Khittel, of Munich, who determined its principal proximate constituents, among which he claimed to have obtained a volatile alkaloid upon which the poisonous properties of the plant depended; but of this he failed to give any proof. In 1865, Prof. John M. Maisch, of Philadelphia, obtained from the fresh leaves of the plant, a new volatile, organic acid, which he named *Toxicodendric acid*, and fully

established that it was to the presence of this principle the plant owed its peculiar poisonous effects. Prof. Maish failed to obtain any evidence of the presence of a volatile alkaloid (Proc. Amer. Pharm. Assoc., 1865, 166). Several cases of poisoning of children who have eaten the fruit of this plant, have been reported.

The beautiful climbing plant *Gelsemium sempervirens*, or Yellow jasmine, a native of the South, was brought to the notice of the profession by an accident, in which a decoction of the root was administered for that of another plant. Its claims as a therapeutic agent were strongly urged upon the profession by Prof. Wm. Procter, in 1852 (Amer. Journ. Pharm., 1852, 307). This plant is now not only used quite generally by the profession of this country, but has found favor with the profession of Europe, having been first employed there more especially as a remedy for neuralgia. Its physiological effects were very carefully studied by Prof. Bartholow, of Cincinnati, in 1870 (London Practitioner, Oct. 1870); and very recently by Drs. Ringer and Murrell, of University College, England (Lancet, March and April, 1876). The first attempt to determine the chemical composition of the root of this plant was made in 1854, by M. H. Kollock (Amer. Journ. Pharm., 1855, 197). It was again examined in 1868, by C. L. Eberle (Ibid., 1869, 35). Both these gentlemen, however, failed to isolate the active principle. In 1869, Dr. T. G. Wormley obtained from the plant a new alkaloid, *gelseminia*, and an organic acid, *gelseminic acid*, the properties of both of which he fully described in the American Journal of Pharmacy for January, 1870. This paper also contains a report of a case of poisoning by the fluid extract of the plant, in which the alkaloid was recovered some months after death. On physiological grounds, Drs. Ringer and Murrell are inclined to the view that the plant contains two active principles, one capable of paralyzing, the other of exciting, the spinal cord.

An indigenous plant, used more especially as a domestic remedy, that early received chemical attention was the Prickly ash, *Xanthoxylum fraxineum*, which was examined in 1829, by Dr. Edward Staples, who found that it owed its active properties to the presence of a peculiar crystallizable principle which he named *xanthoxyline*.(Amer. Journ. Pharm., i. 163). After the discovery of berberina and its identity with xanthopicrite had been shown, it was generally believed that Dr. Staples's xanthoxyline was identical with berberina, especially when the wide distribution of this alkaloid became known; but Mr. Perrins, who first pointed out the identity of the two former alkaloids, states that xanthoxyline is an entirely distinct principle (Amer. Journ. Pharm., 1863, 459, note).

In connection with this early contribution of Dr. Staples may be mentioned that of Dr. J. F. Dana, who in 1819 discovered the existence of the animal alkaloid *cantharidine* in the Potato fly, *Lytta vittata*, the alkaloid having been first obtained in 1812 by Robiquet from the Spanish fly, *L. vesicatoria*. Other American contributions to the chemistry of cantharidine have been made by Prof. Procter, in 1852; by Wm. B. Warner, of Maryland, in 1856; and by Prof. Maisch, in 1872.

A stately American tree, named from its large and beautiful flower, the Tulip tree or *Liriodendron tulipifera*, affords a bark which was recommended to the profession by Dr. Young, of Philadelphia, in 1792, as a substitute for Peruvian bark in intermittent fevers, and in diseases requiring a gentle stimulant and tonic. In 1831, Prof. Emmet, of the University of Virginia, obtained from this bark a neutral, bitter principle

which he named *liriodendrin*, and which he described as a white crystallizable solid (Amer. Journ. Pharm., iii. 5).

Apocynum cannabinum, or Indian hemp, long known as a powerful emetic and cathartic, was examined chemically by Dr. Knopp, who found it to contain, among other proximate constituents, a peculiar, bitter, active principle to which he gave the name *apocynin*. This plant was subsequently examined by Dr. Griscom (Amer. Journ. Med. Sci., May, 1836). This plant is different from *Cannabis indica*, also popularly known as Indian hemp, which was examined chemically in 1865, by Prof. Wm. Procter (Amer. Journ. Pharm., 1865, 23).

The American water hemlock, *Cicuta maculata*, found abundantly throughout the United States, was examined in 1855, by Jos. E. Young, who found it to contain a peculiar acid (probably the *coniic* acid of Perschier), and the volatile alkaloid *conine*, first obtained from conium maculatum, by Geiger, in 1831.

Wahoo, *Euonymus atropurpureus*, so well known throughout the Western States, and sometimes called "burning bush," from the brilliancy of its crimson fruit, was made the subject of a very elaborate chemical examination by Wm. F. Wenzell, in 1862, who found it to contain a peculiar basic principle, which he named *Euonymine*, and a new organic acid, *euonic acid* (Amer. Journ. Pharm., xxxiv. 387).

Many other American plants have contributed to the wants of the physician, and have been the subjects of chemical examination, but special reference to them is necessarily omitted.

We now come to consider the history of the discovery of a compound which is not only interesting in itself, but is more especially so on account of its subsequent applications and the important position it now holds in the medical world.

In 1831, Dr. Samuel Guthrie, of Sackett's Harbor, N. Y., a man of unusual chemical knowledge for his time, discovered a substance which he prepared by distilling a mixture of chloride of lime and alcohol, and an account of which he published in the American Journal of Sciences, Oct. 1831, under the title "A new mode of preparing a spirituous solution of chloric ether." In this paper Dr. Guthrie states that in order to ascertain the effect of this substance in full doses on the healthy subject, and thus discover its probable value as a medicine, he had, during the last six months, administered it to a great number of persons, not only very freely, but frequently to the point of intoxication, and that the effects were grateful both to the palate and the stomach, and he concluded that "it would seem to promise much as a remedy in cases requiring a safe, quick, energetic, and palatable stimulant." His attention was, as he states, first directed to this subject by a statement in Prof. Silliman's Elements of Chemistry (vol. ii. p. 20), then just published, to the effect that an alcoholic solution of chloric ether, when diluted, was a grateful diffusible stimulant and might probably be introduced in medicine.

Prof. Silliman distributed samples of this substance to Dr. Eli Ives, of the Medical Department of Yale College, and to others, to be used in their practice. Under date of January 2, 1832, Dr. Ives reported that he had administered it in a number of cases with marked advantage, and had also used it by inhalation with good results (Amer. Journ. Sci., xxi. 406). The product thus produced by Dr. Guthrie was regarded by him at the time as the substance then known as "chloric ether" or "Dutch liquid," whereas it was an entirely new and distinct substanee, that now

known as *chloroform*. Chloroform was also discovered by Soubeiran, of France, and an account of it published in February, 1831, under the name of *Ether bichlorique*. So, also, Liebig, in 1832, made another independent discovery of the same substance, naming it *Chloride of carbon*. It was named chloroform by Dumas, who discovered its true chemical constitution in 1834. A committee of the Medico-Chirurgical Society of Edinburgh awarded Dr. Guthrie the credit of having first published an account of its therapeutical effects as a diffusible stimulant in 1832 (Amer. Journ. Sci. (2) vii. 143).

As this substance afterwards became a prominent agent in producing anæsthesia, it leads us naturally, but very briefly, to notice the use of this and other substances inhaled for anæsthetic purposes, and the part which Americans have taken in a discovery which has proved an inestimable blessing to mankind.

In this memorial year, we naturally follow the years back to the beginning of the century we commemorate, and find that in 1776, or just one hundred years ago, Dr. Priestley, who had previously made the brilliant discovery of oxygen, discovered *Nitrous Oxide*, which he called *Dephlogisticated Nitrous Air*. In 1779, Sir Humphry Davy, then a very young man, entered upon a series of experiments in Bristol with this nitrous air, which he named nitrous oxide, and on the 11th of April of that year, made the first inhalation of the gas, and recorded its effects upon himself. By his investigations he ascertained its exhilarating effect, and discovered its power, when inhaled, to remove intense physical pain. His remarkable generalization from his experiments was expressed in the following oft-quoted words: "As nitrous oxide in its extensive application appears capable of destroying physical pain, it may probably be used with advantage during surgical operations in which no great effusion of blood takes place." (Researches, etc., concerning Nitrous Oxide and its Respiration, Bristol, June, 1800.) While this suggestion appears to have been forgotten, yet nitrous oxide became widely known and used as a stimulant, and its administration as "laughing gas" was a matter of popular exhibition. In like manner, ether, the date of the first inhalation of which is in some obscurity, was used for the same purpose in the United States, as mentioned by the earlier writers on chemistry. In the experiments with both nitrous oxide and ether, there were cases in which these agents produced perfect insensibility, but the anæsthetic condition was not specially observed.

In the fall of 1844, Horace Wells, a dentist of Hartford, having witnessed an exhibition of the inhalation of nitrous oxide, and observed that a person under the influence of the gas was injured without being conscious of suffering, boldly inhaled the gas, and had a tooth removed without sense of pain, and gave it to others for the same purpose, with similar results. Thus the suggestion of Sir Humphry Davy in Bristol, England, published in 1800, was realized by Horace Wells at Hartford, Conn., in 1844.

In 1846, Wm. T. G. Morton, a dentist of Boston, a former student of Wells, and aware of his labors with nitrous oxide, commenced experiments with ether for the same end. The administration, in the Massachusetts Hospital, of ether by inhalation to a patient upon whom the eminent Dr. John C. Warren performed a surgical operation, authenticated it as an anæsthetic agent to the surgical and medical profession, and from that time the knowledge and practice of anæsthesia extended rapidly over the world.

As already shown, chloroform was employed by inhalation by Dr. Ives, of New Haven, in his practice in the winter of 1831–32 with marked benefit. In March, 1847, M. Flourens experimented with this agent upon lower animals, and in November of the same year the distinguished Prof. James Y. Simpson, of the University of Edinburgh, employed it as an anæsthetic agent with success, and introduced it into surgical and obstetrical practice.

Thus, in summary, we find that anæsthesia, first suggested by Sir Humphry Davy, in 1800, was demonstrated with nitrous oxide as an agent, by Horace Wells, in 1844; with ether as an agent, by Wm. T. G. Morton, in 1846; and with chloroform, by Sir James Y. Simpson, in 1847.

The next American chemical contribution to medicine that we may mention, is that on the "Origin of Urea in the Body," by Prof. John C. Draper, of the University of the City of New York (New York Journal of Medicine, Feb. 1856). In this paper the author shows the error in the statement of Liebig that muscular action increases the amount of urea secreted. The process employed was the decomposition of urea by nitroso-nitric acid, and weighing the carbonic acid produced as carbonate of baryta. The results obtained by Prof. Draper have since been verified by Fick and Wislicenus, but the credit of the first disproval of the statement of Liebig belongs to Dr. Draper.

Dr. Draper has also contributed papers, which may be mentioned in this connection, on "Products of Respiration," New York Med. Times, July, 1856; "Insensible Perspiration," Proceedings of the New York Academy of Medicine, May, 1864; "The Heat produced in the Body, and the Effects of Exposure to Cold," American Journal Science and Arts, Dec. 1872.

The last contribution we shall mention in this connection, is a valuable paper in the department of Physiological Chemistry, entitled "Experimental Researches into a new Excretory Function of the Liver," by Professor Austin Flint, Jr., widely known in the field of experimental physiology. This paper was published in the American Journal of the Medical Sciences for October, 1862; and afterwards presented to the French Academy of Sciences, from which it received in 1869 honorable mention and an award of 1500 francs. The important discoveries put forth in this memoir were the production of cholesterine in the physiological wear of the brain and nervous tissue, and its elimination by the liver, and discharge from the body in the form of stercorine. Dr. Flint's researches and interesting conclusions upon this subject have lately been confirmed in Germany, by experiments in which cholesteræmia has been produced in animals by injection of cholesterine into the blood.

TOXICOLOGY.

We now enter upon the other and not less important branch of the subject assigned us, namely that of TOXICOLOGY. This science is one of the highest moment to the race. While health and life are assailed by various diseases, by the ill-adjustment of outward circumstances, such as climate, locality and the like, by the unsuitableness of food and drink, or by an excessive use of these, and by a thousand other harmful conditions, these

assaults are generally made by slow and noticeable approaches, and are within the ken of the physician. But there have always lurked in the mineral and organic kingdoms, foes which may be likened to assassins who spring upon the unwary and destroy life as by a secret blow. These assailants are the poisons, the very Thugs of nature.

Before the present century little was known of poisons beyond their deadly effects and the attending physiological circumstances. Indeed, any true knowledge of poisons was unattainable until the advent of Chemistry as an exact science. Poisons are naturally grouped into two kinds—inorganic and organic.

In noticing the inorganic or mineral poisons, that one which holds the highest position in historical toxicology, and the one which until recently has been used as a toxic agent very much more than any other, is *Arsenic*. Although known in its metallic state, and as arsenious acid, as early as the eighth century, to Geber, the Arabian, and although it had been used as a poison for centuries, yet so little progress had been made in regard to its chemical detection under these circumstances, that Sir R. Christison, as late as 1824, declared that the tests for arsenic at that time in general use were so fallacious, when applied to complex mixtures, as to be unfit for medico-legal investigations. He then proposed a process for the detection of this metal which, as modified by Fresenius and Babo, continues in use to the present day. At the time of introducing this method, Prof. Christison remarked that by it he was able to detect the one-sixteenth of a grain of the poison. This, at the time, was regarded as a great triumph of analytical skill. Not long before this (1795) Dr. Black stated that one grain was the least he could detect; and at a somewhat earlier period, yet less than a century since (1786), Hahnemann stated that ten grains was the least quantity he could recover.

In 1836, Mr. Marsh, of Woolwich, England, proposed for the detection of this metal, a method which has since been known by his name, and which has proved of the highest value in chemico-legal practice. As originally employed by Mr. Marsh, this test was restricted to obtaining deposits of the metal from the ignited jet of the arsenide of hydrogen; but in 1841 Berzelius proposed the reduction of the arsenical gas by heat applied to the exit tube of the apparatus, and it has been found that this method is even more delicate than that proposed by Marsh. In 1841 Dr. Hugo Reinsch proposed, for the detection of this metal, his copper test, which has proved a most admirable method for the recovery of the poison, especially from complex organic mixtures. In point of delicacy, as now employed, this test is not inferior to the process of Marsh, and it has in certain cases even the advantage over the latter in simplicity of application. The two tests now mentioned, both in regard to simplicity of application and delicacy of reaction, leave little or nothing more to be desired in regard to the recovery and identification of this poison.

One of the first American contributions relating to the detection of arsenic was by Prof. James F. Dana, a graduate of Harvard University, who studied chemistry in London, and was afterwards Professor of Chemistry in Dartmouth College and in the College of Physicians and Surgeons, New York. As early as 1816, he prepared a paper on the "Tests for Arsenic," for which he received the award of the Boylston prize. In 1818, Dr. Thomas Cooper announced the use of chromate of potash as a test for arsenic; but it did not prove to be a distinctive test. In the same year, he read a paper on the subject before the American Philosophical Society (Amer. Journ. Sci., iv. 16). In 1830, Prof. John

P. Emmet, of the University of Virginia, proposed iodide of potassium as a test for this metal. In the next year (1831) Dr. Lewis Feuchtwanger published a paper entitled "Remarks on Arsenic, with drawings of the color of its precipitates," in which he gave a full account of the processes then known for the detection of this poison (Amer. Journ. Sci., xix. 339). An important and original contribution on this subject was made in 1832, by Prof. J. K. Mitchell, of Philadelphia. In this paper, "On the Properties of Arsenic," Dr. Mitchell determined the specific gravity of the different varieties of arsenious acid; its solubility under various conditions; and the vaporizing temperature of metallic arsenic and of arsenious acid (Amer. Journ. Med. Sci., x. 126).

The next contribution to be mentioned is that "On the Detection of Arsenic in Medico-Legal Investigations," by Dr. Wm. R. Fisher, of the University of Maryland, in a paper read in 1836 before the Maryland Academy of Science and Literature, and published in their Transactions (vol. i. p. 117). In 1838, Dr. Robert B. Hall published a Summary of Experiments upon dogs, with hydrated peroxide of iron as an antidote in arsenical poisoning (Amer. Journ. Pharm., x. 263). And in 1840, Dr. Fisher, already mentioned, contributed a paper on the same subject (Ibid., xii. 1). In 1841, Prof. J. Lawrence Smith, of Louisville (to whom science is indebted for many original researches, and whose special investigations of meteoric bodies have given him a wide and lasting reputation), when a student in Paris, prepared a valuable paper On the Tests and Antidotes for Arsenic (Am. Journ. Sci., 40, 278). Two years later (1843), Dr. D. P. Gardner, Professor of Chemistry in Hampden-Sidney College, Va., contributed an elaborate paper On the Application of Reinsch's test for detecting Arsenic in Medico-Legal Investigations (Amer. Journ. Sci., 44, 240). In 1862, Charles H. Porter, Professor of Chemistry and Medical Jurisprudence, Albany Medical College, presented to the Medical Society of New York an excellent paper entitled Medico-Legal Contributions on Arsenic, which contains reports of a number of cases of arsenical poisoning, together with an account of the methods employed in their chemical examination.

We next notice a very valuable contribution by Prof. John C. Draper, of the University of the City of New York, On the Quantitative Determination of Arsenic, published in the American Chemist for June, 1872. Professor Draper suggests a modification of Marsh's apparatus, and the use of a ribbon of magnesium for decomposing the arsenical solution; and, also, the use of a fagot of platinum wire on which the arsenic forms a coating, the weight of which can be determined. By re-heating the fagot in dry oxygen, the arsenic is obtained in the form of oxide, which may be dissolved in water and submitted to the usual tests. In July of the same year, Dr. Draper published in the same journal a paper On the Distribution of Arsenic in the Body. Another contribution to this subject that deserves mention, is a record of The Chemical Testimony in the Sherman Poisoning Case, by Prof. George F. Barker, of the University of Pennsylvania (Amer. Chemist, June, 1872). This paper contains a detailed account of the methods pursued and results obtained in the examination of the different tissues submitted for analysis. In this case, a quantity of arsenic, corresponding to about five grains for the entire organ, was obtained from a portion of the liver. The bodies of four (4) of the eleven (11) persons supposed to have been poisoned by Mrs. Sherman were examined by Prof. Barker, and arsenic found in each.

Having thus noticed the principal American contributions relative to arsenic, it is proper in this connection to refer to some of the more important American contributions relating to other poisons.

In 1827, Prof. Robert Hare proposed a method for determining the presence of opium by the reaction of one of its constituents, meconic acid, in striking a red color with a persalt of iron. He asserted that this test would show the presence of laudanum when only ten (10) drops were contained in one-half gallon of water (Amer. Journ. Sci., xii. 290). With but little modification this test is the one employed at the present time for the detection of opium.

In 1856, Dr. Lewis H. Steiner, of Baltimore, made a report to the American Medical Association, On Strychnia, in which, in addition to a discussion of the chemistry of the subject, he gives a detailed history of the noted case of Dr. Gardner, of Washington, who destroyed himself with that poison. In a paper On the Chemical Reactions of Strychnia, published by Dr. T. G. Wormley, in 1859, in the American Journal of Science, the relative delicacy of the various tests for this poison is pointed out. The fact that the color-reaction of strychnine is interfered with by the presence of morphine, having first been noticed by A. W. Brieger in 1850, this interference is fully considered in this paper, and the conclusion reached, that the interference increases both with the relative proportion and absolute quantity of morphine in the mixture submitted to the test. Another paper to be mentioned in this immediate connection, is that of Prof. John J. Reese, On the Detection of Strychnia as a Poison, and the Influence of Morphia in Disguising the usual Color-test, published in the American Journal of the Medical Sciences for October, 1861. So also in this connection may be mentioned a valuable contribution On the Behavior of the Color-test for Strychnine, with other Vegetable and Animal Proximate Principles, by Dr. Thomas E. Jenkins, of Louisville, Ky. (Semi-monthly Med. News, April, 1859). The behavior of this test with a number of proximate principles other than strychnine, was first examined in 1856, by M. Eboli, Professor of Chemistry at the Academy of Medicine, Lima. Dr. Jenkins so extended this examination as to include about fifty of these principles; and Prof. Wm. A. Guy, of London, in 1861 investigated some sixteen additional substances.

Another contribution to this subject is a Report of a Trial for Poisoning by Strychnia, by Prof. Geo. F. Barker, recorded in the American Journal of the Medical Sciences for October, 1864. In this paper Prof. Barker gives a very complete history of a case remarkable in that violent symptoms were present in about three minutes after the poison had been taken by an adult, the effects thus manifesting themselves perhaps more rapidly than in any other instance yet reported of poisoning by this substance.

An elaborate paper entitled Experiments of Poisoning with Vegetable Alkaloids, by Dr. J. H. Salisbury, was published in the American Journal of the Medical Sciences for 1862. In regard to the limit of the reactions of poisons and other principles, with chemical reagents, Dr. T. G. Wormley has contributed papers on the reactions of the following: Atropine, Chemical News, London, June, 1860; Brucine, Ibid., July, 1860; Morphine, Ibid., Sept. 1860; Narcotine and Meconic Acid, Ibid., Sept. 1860; Corrosive Sublimate, Ibid., Sept. 1860; Veratrine, Ohio Med. and Surg. Journ., vol. xii., No. 6; Nicotine and Daturine, Ibid., vol. xiii., No. 1; Solanine, Ibid., vol. xiii., No. 2; Codeine, Meconine,

Narceine, and Aconitine, Ibid., vol. xiii., No. 4; Conine, Ibid., vol. xiv., No. 1; Oxalic Acid, Ibid., vol. xiv., No. 5.

Mention may next be made of a curious plant, *Erythroxylon coca*, the leaves of which have arrested considerable attention because of their use by the Indians of Peru for the purpose of producing excitement, and giving strength for prolonged physical exertion. Dr. Samuel R. Percy, of New York, presented a paper on this subject before the N. Y. Academy of Medicine, Dec. 2, 1857, and exhibited fine colorless crystals of the alkaloid of the plant, for which he proposed the name *Erythroxyline* (Amer. Med. Times, Nov. 1860). In 1860 Prof. Woehler and Dr. Nieman, of Gottingen, obtained the same alkaloid, giving it the name *cocaine*.

In 1866, Dr. Percy, of New York, presented a paper to the American Medical Association, On Digitaline, its Chemical, Physiological, and Therapeutic Action, for which the Association awarded a prize; and, in 1868, the same gentleman received a prize from the Alumni Association of the Medical Department of Columbia College for a paper On Atropia, its Chemical, Physiological, and Therapeutic Action, with Experiments instituted to ascertain its Toxicological Properties. In January, 1871, Prof. John J. Reese, of Philadelphia, published a communication On the Antagonism of Poisons, in the American Journal of the Medical Sciences, in which he examined the antagonism of morphia with hydrocyanic acid, atropia, strychnia, aconitia, and arsenic, and also of strychnia with tobacco, aconite, iodine, and Calabar bean. For the destruction of the organic tissues, in searching for poisons in medico-legal investigations, Prof. Henry Wurtz, in 1851, proposed the use of bromine as an agent possessing certain advantages over the ordinary agents used for this purpose (Silliman's Journal (2), xi. 405).

We now notice a very interesting and valuable paper on Experimental Researches relative to Corroval and Vao, two new varieties of Woorara, the South American Arrow Poison; by Drs. Wm. A. Hammond and S. Weir Mitchell, published in the American Journal of the Medical Sciences, July, 1859. This is an original and exhaustive examination of the physiological effects, and the chemical properties and physical characters, of these varieties of Woorara. The authors extracted from both varieties an alkaloid, for which they proposed the name *corrovalia*, obtaining it in larger quantity from the variety corroval. This substance was not obtained in a crystalline state, nor were any of its salts. One of the authors of the last-named paper, Dr. S. Weir Mitchell, published in the Smithsonian Contributions, vol. xii. (1860), a very elaborate and complete monograph, entitled, Researches upon the Venom of the Rattlesnake. This contribution is marked by the same patient and thorough research which characterizes the other scientific labors of this original investigator. It considers the anatomy of the venom apparatus, the physiological mechanism of the bite, the toxicological action of the venom on warm-blooded animals, and the various antidotes for the poison. His chemical investigations show the toxicological element of the venom to be a peculiar albuminoid principle, which he names *crotaline*.

Again, in 1868, Dr. Mitchell instituted a series of experiments on the Insusceptibility of Pigeons to the Toxic Action of Opium, in which he showed that this bird was almost wholly insusceptible to the action of that drug. The same immunity was observed whether the drug itself, or morphia, was employed, and also whether it was administered internally or employed hypodermically. In his final experiment, Dr. Mitchell

administered to a large pigeon twenty-one grains of powdered opium, without producing any evidence of opium poisoning (Amer. Journ. of the Med. Sci., Jan. 1869). Dr. B. W. Richardson, of London, on repeating Dr. Mitchell's experiments, fully confirmed his results. As a comparison of the relative susceptibility of the pigeon and the child, Dr. Richardson states that a pigeon can receive at once as much opium as would produce dangerous or even fatal symptoms, if divided equally and administered to twenty children under one year old, the weight of the bird being two hundred times less than the combined weight of the children (Brit. and For. Med. Chir. Rev., April, 1869). Continuing his researches, Dr. Mitchell extended his experiments to the physiological effects of the derivative alkaloids of opium, including morphia, narcotina, thebaia, meconine, codeia, narceia, and cryptopia, employed both internally and subcutaneously. In these experiments, Dr. Mitchell obtained some very interesting and novel results. Thus, he found that while opium, which is a poison to man, is with difficulty hurtful to the pigeon; on the other hand, narcotina, which is nearly inert in man, is fatal to birds (Amer. Journ. of the Med. Sci., Jan. 1870).

We next notice some very original and interesting investigations of Dr. James Blake, of San Francisco, who has been engaged for many years in examining the connection between Isomorphism, Molecular Weight, and Physiological Action (Amer. Journ. Sci. (2) viii. p. 193). Dr. Blake has investigated the effects of compounds or salts of forty (40) of the elements, including substances contained in all the more important isomorphous groups, and in all of these, with the exception of the compounds of potassium and ammonia, finds that when introduced directly into the blood of living animals, the substances in the same isomorphous group exert analogous effects; and also that amongst the more purely metallic elements, the intensity of physiological action is in proportion to the atomic weight of the substance compared with other substances in the same isomorphous group. From experiments made by others, Dr. Blake believes that the same law will apply to organic or carbon compounds, and that living matter will be found to be a valuable reagent for elucidating their molecular relations. His latest researches on Lanthanium and Didymium place the former evidently in the magnesium group and the latter with aluminium. These researches, with those of Drs. Crum Brown and Fraser, and with those of Dr. Richardson, are in a new field of inquiry, and promise very interesting and important results to science.

Having thus glanced at the more important American contributions to toxicology, the way is prepared to take a broader view of this science, and observe the progress of its development, especially in its chemical features. This progress will be seen to be greater in regard to the organic poisons, the marked advance in methods of chemical analysis having made such progress possible.

At the opening of the present century, the fact that the toxic effect of certain vegetable poisons was due to the agency of a peculiar active principle, resident in the plant, had not been determined. The vegetable substance in which the existence of a principle of this kind was first observed was opium, in which Sertürner and also perhaps Seguin in 1804 recognized the presence of a new substance; but it was not until 1817 that Sertürner obtained it in a pure state, and examined its properties. He found that the alcoholic solution of this new principle acted upon

vegetable colors like solutions of the mineral alkalies, and that the substance combined directly with acids, forming neutral salts which were soluble in water, and that it was precipitated from solutions of its salts by the mineral alkalies. To this substance Sertürner gave the name *morphine*, and from the properties just mentioned he regarded it as a kind of alkali; hence the name vegeto-alkali or alkaloid for principles of this kind.

Very soon after the discovery of morphine it was found that nux vomica, white hellebore, cinchona bark, belladonna, tobacco, and certain other vegetable products which had been long known as capable of exerting marked physiological effects, owed their activity to the presence of similar alkaline principles. The number of such natural principles now known is quite considerable. Since 1848 a great number of organic alkalies have been obtained artificially, some of which rival potash and soda in the degree of their alkalinity. The study of these artificial alkaloids has thrown much light upon the constitution of the natural alkaloids, which is, as yet, imperfectly understood.

The discovery of the natural alkaloids has been of great service to the physician, giving him a more concentrated and manageable form of medicine; but to the toxicological chemist this discovery has been of the very highest value, enabling him in cases of poisoning by crude vegetable substances, in just so far as he can recover the alkaloid or active principle from complex mixtures (such as the contents of the stomach), and can separate and determine it by special chemical properties, to identify the toxic substance employed. There are, however, many vegetable and animal poisons, the exact nature of the active principle of which has not yet been determined.

Formerly, about the only method of detecting vegetable poisons was by means of the physical and botanical characters of the subtance taken, such as the leaves, seeds, etc., and this method is yet of service in furnishing corroborative evidence in cases even in which the nature of the peculiar principle is known. It is obvious that in poisoning by crude vegetable and animal substances, we can determine the presence of the poison by chemical methods only, first, when we know that the substance contains an alkaloid or other principle peculiar to itself; second, when we are able to recover this principle from complex mixtures; and third, when we are acquainted with one or more chemical reactions characteristic of this principle. Thus, in poisoning by opium, we cannot prove the existence of opium as a whole, but only inferentially, by proving the presence of a principle peculiar to this drug. Our success in the discovery of organic poisons, where the existence of a peculiar principle is already known, depends largely on our ability to recover such principle from complex mixtures in a state sufficiently pure for the application of special tests.

It was not until 1851 that any real progress was made in this direction, when Prof. Stas, of Brussels, introduced a systematic method for such recovery. This method has proved of the highest importance, and marks an era in toxicological science. It is based upon the fact that the salts of the alkaloids, as a class, are soluble in water and alcohol, but are insoluble in ether; and that these salts when in solution are readily decomposed by the mineral alkalies with the elimination of the alkaloids, which in their free and uncombined state are more or less readily soluble in ether. In any given case therefore, in so far as the active principle or alkaloid

is soluble in ether, and this liquid fails to extract foreign animal and vegetable matter, in just so far can we obtain the alkaloid in its pure state. Professor Stas successfully applied his method for the recovery of the principal alkaloids likely to be met with in chemico-legal investigations, employing for this purpose the usual extracts of the plants in which they are found. Professor Otto, of Brunswick, proposed to modify the method of Stas, in the case of the fixed alkaloids, by first washing the acid aqueous solution of the alkaloidal salt with ether as long as this fluid was colored; the solution is then rendered alkaline and the liberated alkaloid extracted with ether as before proposed. Professor Otto claimed, and justly, that in this manner the alkaloid might be obtained in a state of greater purity, and almost invariably in a crystallized condition.

In 1853, Professors Graham and Hoffman, of London, proposed a method for the recovery of strychnine from organic mixtures, which was afterwards extended to other alkaloids; it is based upon the fact that when a solution of strychnine in its free state is agitated with charcoal, the charcoal absorbs the poison and yields it up to boiling alcohol (Quart. Journ. Chem. Soc., 1853). In practice, in chemico-legal investigations, this method is inferior to that of Stas. In 1856, Messrs. Rogers and Girdwood, of London, proposed the use of chloroform instead of ether, as advised by Stas, for the extraction of the alkaloids. They also proposed to destroy the last traces of foreign matter by charring the chloroform residue with concentrated sulphuric acid over a water-bath (Lancet, London, June, 1856). The use of chloroform as advised by these gentlemen has proved of value in researches of this kind, since it is a better solvent of most of the alkaloids than ether, and has therefore an advantage in certain cases; but, on the other hand, it has sometimes the disadvantage of taking up more freely than ether foreign animal and vegetable matters. Another method for the extraction of the alkaloids from complex mixtures is that of Usler and Erdmann, who proposed the use of amylic alcohol, the principle of the process being much the same as in the method of Stas. Amylic alcohol is especially adapted to the recovery of morphine, solanine, and certain other alkaloids, which are more or less freely soluble in this liquid, whereas they are but very sparingly soluble both in ether and chloroform, and therefore are but imperfectly extracted by these liquids.

In 1862, Professor Thomas Graham, of London, in his very important contribution on liquid diffusion, showed that moist organic membranes have the remarkable property of separating crystallizable substances when in solution from such as are uncrystallizable, the former readily passing through such membranes when surrounded by a liquid, whereas the latter fail to pass or pass only very slowly. These classes of substances he named respectively *crystalloids* and *colloids*, and to this method of separation he applied the term *dialysis*. This method is applicable to both inorganic and organic bodies, and is often found very useful in toxicological investigations.

The latest contribution to this department of research is that of Prof. Dragendorff, of the University of Dorpat, who, in 1868, proposed a very elaborate and exhaustive method for the extraction of the alkaloids and similar principles, and for their separation from each other, based upon their behavior with petroleum-naphtha, benzole, chloroform, and amylic alcohol, dividing them into several groups according as they are affected by these different liquids under certain specified conditions.

From this brief historical sketch, we learn that very considerable attention has been directed to this important and essential part of toxicological chemistry; and, it may be added, the results have been such as to leave little to be desired in regard to the recovery of a large number of organic poisons. We are now prepared to take a rapid survey of the progress made in regard to the special identification of poisons by chemical and other tests. Even less than a third of a century ago, there were but few of the organic poisons for which special and unerring tests were known, especially when present in the minute quantity usually met with in chemico-legal investigations.

In September, 1843, E. Marchand made the important discovery that if strychnine be treated with concentrated sulphuric acid containing a little nitric acid and peroxide of lead, it dissolves with the production of a series of colors peculiar to that alkaloid. The tests employed for the detection of this poison prior to the discovery of this color reaction, which has since been known as the color-test, gave reactions more or less common to substances other than strychnine. In fact, this color-test is the only one yet known the reaction of which, taken alone, is peculiar to strychnine. It was considered a marvel of delicacy of reaction when Marchand announced that this test would reveal the presence of a quantity of strychnine not exceeding the one-thousandth of a grain in weight. This test has since been modified by Mack, Otto, and others, by substituting for the nitric acid and lead compound other oxidizing compounds; and it will now, in the hands of a skilful manipulator, show the presence of strychnine when in quantity not exceeding, perhaps, the one-millionth of a grain.

The discovery of this test did much to stimulate chemists to search for special or characteristic tests for other alkaloids and vegetable principles likely to be encountered in chemico-legal investigations, and in many instances with success. Much remains, however, to be done in this direction, even in regard to some very well known poisons of this class. There are some poisons, the presence of which may be determined by what is known as a combination of tests, no one of which is in itself peculiar or exclusive; but there are others for which we have as yet neither peculiar and distinctive tests, nor any peculiar combination of tests for their detection, especially when present in minute quantity.

It is less than a quarter of a century since the aid of the *microscope* was, to any marked extent, invoked in this department of research, yet within this comparatively brief period its use has very greatly extended our means of determining the specific nature of the results of chemical tests. This instrument not only often enables us to determine the true nature of a precipitate or sublimate by its crystalline or other form, the character of which would otherwise be doubtful, but it enables us to recognize and identify certain substances when present in quantities so minute as to be far beyond the reach of the ordinary methods of examination. Thus by micro-chemical analysis we are able to identify with absolute certainty the reaction of the one hundred thousandth part of a grain of hydrocyanic acid, and of certain other poisons in quantity equally minute. Even a sublimate, consisting of a few crystals, each of which does not exceed the one hundred millionth of a grain in weight, may, under certain conditions, serve to characterize the presence of arsenic beyond a question of doubt. The chief contributors to the micro-chemistry of poisons have been Professors Guy and Taylor, the eminent

toxicologists of England; Drs. Helwig and Earhard, of Germany; and Professor Wormley, of the United States.

For the final purification and subsequent examination by means of the microscope either directly or under the action of reagents, the process of *sublimation* has been proposed, as applicable to both inorganic and organic substances. In 1858, Professor Wm. A. Guy, of London, called special attention to the process of sublimation for the detection of arsenic, corrosive sublimate, and certain other inorganic poisons; and in 1865, Dr. Helwig, of Mayence, announced that in like manner certain alkaloids and vegetable principles furnished sublimates, some of which were characteristic in their microscopic forms and in their behavior with reagents, and he gave photographic illustrations of many of the forms thus obtained. In 1867, Dr. Guy modified somewhat Helwig's method, extended it to a much larger class of objects, and proposed to add to the diagnostic value of the method by a simple arrangement for noting the temperature at which changes in form and color, and sublimation itself, occur.

The brilliant discoveries of Bunsen and Kirchhoff, in 1859, which enable us by means of *spectrum analysis* to recognize and identify with unerring certainty the elementary forms of matter and certain compounds, even when present in quantities so minute as to be far beyond the reach of the ordinary methods of analysis, have not been without some fruit in the department of chemico-legal investigations. Thus Dr. Bence Jones found by this method thallium in the liver, when the ordinary chemical tests failed to reveal its presence.

It is a proof of the great activity and sagacity displayed in modern science that the spectroscope with its amazing capabilities should so soon be combined with the microscope, an instrument of scarcely less capabilities, thus forming the *micro-spectroscope*, by which we are enabled to make new discoveries of the highest value in Medico-legal Chemistry. For this combination of the two instruments we are chiefly indebted to Mr. H. C. Sorby, who has with its aid determined the spectra of a large number of organic coloring principles when in solutions. One of the most important applications of this instrument thus far made in legal medicine, is that for the detection of blood, its delicacy being such as, according to Mr. Sorby, and as confirmed by our own observations, to reveal the presence of a single corpuscle, or less than the one thirteen millionth of a milligramme, or one five hundred millionth of a grain, of that fluid. Although this method will serve to discriminate the coloring matter of the blood from other coloring principles, yet it does not enable us to distinguish the blood of any one animal, including man, from that of another. This, however, can be done within certain limits, but only within certain limits, by means of the microscope; this instrument enables us to specify with great certainty certain animals, even of the same class, from which the blood was *not* derived, but it does not enable us to *positively individualize* the animal from which it *was* derived.

Our discussion of toxicology would be very incomplete without some notice of the subject of the *absorption* of poisons. Prior to the important discoveries of Magendie on venous absorption, in 1809, it was believed that all poisons produced their effects by impressions transmitted through the nerves. The chief argument in support of this view, was that the rapidity of action of certain poisons was incompatible with any other mode of transmission. Dr. Blake successfully met this argument, and showed from experiments that sufficient time elapsed for absorption even

in the case of those substances the most rapid in their action, such as hydrocyanic acid and conine. Through the labors and experiments of Dr. Blake, Sir Benj. Brodie, Sir Robert Christison, M. Bernard, and other physiologists, the views of Magendie were confirmed, and it was accepted that the entrance of the poison into the blood was a condition essential to its action.

That certain substances were absorbed and widely distributed, was early observed from the color imparted to various tissues of the body, and to the urine, by certain coloring principles, as indigo, picric acid, and the like; and by the characteristic odor perceived throughout the body in poisoning by prussic acid and other odorous substances. When we consider how minute is the quantity of certain poisons required to destroy life, the imperfect character of the methods of analysis early employed, and the fact that certain poisons may soon pass beyond recovery, it is not surprising that the progress in recovering poisons from the blood and tissues was somewhat slow. We find, however, that in 1821, Tiedeman and Gmelin found lead, mercury, and barium in the blood of animals poisoned by salts of these metals; that, in 1827, Wœhler recovered certain administered poisons from the urine; and that, in 1829, Wibmer satisfactorily proved the presence of lead in the tissues of animals poisoned by that metal. It was reserved, however, for Professor Orfila, whose original and profound labors in this department have brought honor upon science, to show the absorption and distribution of arsenic throughout the animal body. In January, 1839, this distinguished investigator announced to the Parisian Academy of Medicine, that in poisoning by this substance, the arsenic diffuses itself in such quantity that it may be recovered by chemical methods from the blood, tissues, and various secretions of the body. In 1840, he proved these facts to the satisfaction of a committee of the Academy. This discovery inaugurated a new era in medical jurisprudence. Subsequently, Orfila proved that the same wide distribution of poison throughout the body held in regard to mercury, antimony, lead, and other metallic poisons.

It has generally been believed that in the absorption of metallic poisons, and in their deposition in the soft tissues of the body, a larger proportion is to be found in the liver than in any other part, the least proportion being found in the muscles; but, according to the quite recent researches of M. Scolosubroff, absorbed arsenic, both in acute and chronic poisoning, is deposited specially in the nervous system. Thus, if the quantity found in the fresh muscle be taken as 1, that in the liver is 10.8; that in the brain 36.5; and that in the spinal marrow 37.3 (Ann. d'Hygiène, Jan. 1876). Under the present improved methods of analysis, it now rarely happens, in cases of poisoning by mineral substances, that the poison cannot readily be detected in the various organs and tissues of the body; yet it is well known that even in this kind of poisoning the toxic agent may be entirely removed from the body prior to death.

Our experience in regard to the recovery of the vegetable poisons has not been so satisfactory. While there are some of this class which may be readily detected in the blood and tissues, and others that have been found only rarely, there is still a large number that have never as yet been found in the absorbed state.

That all the organic poisons enter the blood and are diffused throughout the body is no longer doubted. The first instance of the recovery of a vegetable alkaloid, after it had undergone absorption, was announced by Stas, as late as in 1845, and less than a third of a century ago; in this

case he recovered morphine from the viscera of a body that had been buried for thirteen months. Many instances have occurred since, however, in which, even under more favorable conditions, there has been a total failure to recover this alkaloid from any part of the body. So, also, in 1851, Stas detected nicotine in the blood of a dog poisoned by that substance, employing his ether process for the extraction of the alkaloid.

Perhaps no one circumstance did so much to call the attention of toxicologists to the subject of the detection of the vegetable poisons in the blood and tissues, as the remarkable trial, in London, of Palmer for the poisoning of Cook by strychnine, in 1856. Prior to May, 1856, according to Prof. A. S. Taylor, in no instance had strychnine been recovered in an absorbed state from the blood, tissues, or soft organs of the body. This trial directed special attention to this poison, and led to its more careful investigation, and from that time instances of its recovery after absorption have become quite frequent. In fact, under the recent improved methods of analysis, a failure to recover this poison in its absorbed state, should rarely happen. Since this time, chemists have been gradually adding to their triumphs in this important department of research, and now authentic instances have been recorded of the recovery and identification by chemical tests, of at least the following alkaloids: morphine, nicotine, strychnine, brucine, atropine, daturine, veratrine, jervine, and conine. It may be added, that considerable difference exists in regard to the readiness with which the different poisons just mentioned may be recovered when in the absorbed state.

That all poisons, except those endowed with corrosive action, have to enter the circulation in certain quantity before producing their peculiar effects, is now universally conceded. We may now inquire what is known of the mode or manner in which when diffused in the blood they destroy life. It is well known that some poisons produce an appreciable change in the physical and chemical properties of the blood, as shown in the difference of color and consistency of that fluid. These changes are well marked in the cases of sulphuretted hydrogen, prussic acid, carbonic acid, chloroform, and conine, under the action of which the blood becomes more liquid and of a darker color. In most of these cases the poisoned blood, when examined by the spectroscope, gives the spectrum of deoxidized blood.

It was long since observed that certain poisons on being introduced into the blood were either wholly, or in great part, decomposed. Thus, Sir R. Christison failed to obtain any chemical evidence of the presence of oxalic acid in the blood of the vena cava of a dog, killed in thirty seconds by the injection of eight grains and a half of that poison into the femoral vein. Even with the improved methods of analysis, chemists have never yet been able to recover this poison, as such, from the blood. In some cases we can very clearly trace the changes which take place in the substance absorbed by the blood. Thus Erdmann and Marchand, in 1842, found that cinnamic acid was converted during its progress through the animal system into hippuric acid; and in 1862, Dr. Letheby found that under like conditions nitro-benzole was changed into aniline. In like manner it has been found that hydride of benzole is changed into benzoic acid, which in its turn becomes converted into hippuric acid. In 1832, Liebig showed that hydrate of chloral under the action of an alkali, was changed into chloroform and formic acid; and in 1868, Liebrich showed that the same change took place when this substance

entered the blood by absorption, and to this change is attributed the peculiar sedative effects of chloral.

Even in regard to the action of strychnine, brucine, morphine, veratrine, nicotine, and certain other organic poisons, which may be recovered from the blood in their unchanged state, it has been claimed by some that they are changed in part at least before they produce their toxic effect, but of this there is no direct proof. When we consider the extremely minute quantity of substances of this kind which may destroy life (a quantity sometimes certainly not exceeding in weight the one three hundred thousandth part of the blood), and the ready demonstration of their presence in the blood after death, it would appear that in certain instances at least, the fatal issue is not dependent upon the decomposition of any part of the toxic agent.

Although the various facts that have been presented are of great value and interest, yet it must be admitted that the whole subject of the final action of poisons is left in great obscurity. While it is believed by all that poisons are absorbed and taken into the circulation, it is found that only some produce any marked changes, physical or chemical, in the blood; and on the other hand, while some poisons are themselves decomposed in that liquid, yet others equally fatal, appear to suffer little or no change. We may trace the destroyer in all its subtle insinuations through the blood and tissues, and see life quickly driven from the body, but we know not *where* nor *how* the fatal stroke is given. These are questions which modern science, with all its refined methods of research, has left unanswered.

In conclusion, it may be said that the field in which the toxicological chemist labors, is one of the highest responsibility. He must not only be consecrated to his science, know all its best methods, and be able to practise them in all their most delicate and skilful manipulations; but he should have a higher consecration to *truth*, ever remembering that in toxicological jurisprudence his words should be weighed in balances even more delicate and exact than those in which he weighs his material substances. Human life on the one hand, and the security of society and the vindication of law on the other, may hang upon the slender thread of a chemical reaction, or tremble in the final adjustment of a most delicate instrument. The highest skill, and a regard for truth that knows no shadow of turning, can alone fit the toxicological chemist to meet the grave responsibilities of his profession.

ADDRESS ON SURGERY.

BY

PAUL F. EVE, M.D.,

PROFESSOR OF OPERATIVE AND CLINICAL SURGERY IN THE UNIVERSITY OF NASHVILLE.

GENTLEMEN OF THE INTERNATIONAL MEDICAL CONGRESS:

THE language of the Aborigines of America has ever been admired for its simplicity and significance. In the State of Mississippi, itself implying the father of all waters, is a County called Itawambi, derived from the title given an Indian Chief, upon whom all possible honors had been conferred, so that nothing more could be done for him. Standing here this day, the representative of the most demonstrative and efficient department of the healing art; the recipient too of many unmerited favors; fully conscious of the inability to do justice to the subject proposed, or satisfactorily improve the illustrious occasion—an event without precedent, and which no living man will ever see again—language fails to convey or words express what is now felt. With all the simplicity of the Indian and the sincerity of the Christian, I would say to you, my professional brethren, who have done so much for me, *Itawambi*.

Precisely fifty years ago, he who is now to address you, landed on Chestnut Street wharf of this city, enquiring for the office of the late distinguished accoucheur, Charles D. Meigs, to become his private pupil; fifty years before that, his father, born in Philadelphia, had been the associate of Rush, Shippen, and James; and now, at the end of those hundred years, the son is invited back to declare before this International Medical Congress, and at the celebration of the first Centennial of these United States, what his countrymen have done for Surgery. Here too in the Medical Department of the University of Pennsylvania, the first chartered Medical College on this Continent, where so many have been taught by Rush and Chapman, Hare and Jackson, Physick and Gibson. To me it is but the coming back to my dear old Alma Mater. Surely "There's a divinity that shapes our ends, rough hew them how we will."

"God moves in a mysterious way,
His wonders to perform;
He plants his footsteps in the seas,
And rides upon the storm."

A mere enumeration of what we have contributed to Surgery, even were that possible during the hour assigned to the subject, might not prove the most profitable occupation of it; and moreover, while this may be the Centennial of our National existence, it is not that of our profession; for, as is well known, the War of Independence left us an impoverished people, almost destitute as regards the sciences, certainly without any peculiar medical literature. Even the reputed father of American Surgery was not admitted a house-surgeon in St. George's Hospital, London, though a private pupil of the celebrated John Hunter, until

1790; nor was he elected Professor of Surgery in the University of Pennsylvania until 1805. It was as late, too, as 1820, forty-four years after the Declaration of Independence, that the taunt was uttered, with probably as much truth as sarcasm, "what does the world yet owe to an American Physician or Surgeon!" Then again, all our early teachers had of necessity to be educated abroad, so that in the very nature of things no national characteristics could have been given to medicine until years after the colonies became the United States. Notwithstanding all this, in a little over fifty years, the sarcasm of Sydney Smith was answered by a professor of Surgery in the city of Paris, M. Chassaignac, remarking as is said to an American medical student, "Sir, you ought to be proud of your country, for at this moment she holds the sceptre of Surgery in the world."

He whom we have ever regarded as the father of American Surgery, Philip Syng Physick, was born in Philadelphia in 1768, and was therefore only eight years old at the declaration of our Independence; he graduated in the literary department of the University of Pennsylvania, received his diploma at the Royal College of Surgeons, London, and the degree of doctor of medicine in Edinburgh, in 1792. Returning home soon after, the appearance of yellow fever, for the first time in Philadelphia, brought him prominently before the public. For services rendered the city hospital in 1794, Dr. Physick was presented with silver plate valued at one thousand dollars.

As early as 1794, he recommended curved forceps holding a needle to secure deep seated arteries. In 1802, he proposed the seton for ununited fractures. In 1836, Mr. Liston gave him credit for this valuable suggestion; and in the Contributions to Practical Surgery, published by Dr. Norris, formerly Surgeon to the Pennsylvania Hospital, in 1873, the seton and its modifications are declared to be safer, speedier and more successful than resection or the caustic.

In 1809, Dr. Physick by a suture removed the projecting duplicated portion of the intestine in Artificial Anus, and thus re-established the integrity of the alimentary canal. Dupuytren's enterotome has since somewhat supplanted the seton.

Physick improved Desault's splint by extending it higher up on the fractured side, thus making extension and counter-extension more in the axis of the broken limb. He was among the first to apply animal ligatures; employing buckskin for this purpose, while his nephew and favorite pupil, Prof. Dorsey, preferred French kid deprived of its tanned cuticle, a substance with which he successfully ligated the femoral artery. Deer sinew torn into shreds of suitable size for the vessel to be ligated, is preferred by others, though silk is generally employed. Animal ligatures certainly irritate less, are readily absorbed, and thereby promote reunion of wounds. In the use of them for some forty years, though not exclusively, the knot of a deer sinew has never been seen, while the metallic ligature or suture ever remains a foreign body in the flesh.

Dr. Physick was the first to employ blisters in gangrene threatening mortification, as in anthrax, or over an inflamed vein The late Prof. Chapman, long his colleague in the University of Pennsylvania, published a case in which he attributed the life of the patient to this suggestion.

He improved the gorget, an instrument employed in his day in lithotomy.

He invented the tonsillotome, in 1848, by which a hazardous operation

has been greatly simplified and made safe. Formerly, attempts were made to cut out the entire tonsils at the imminent risk of fatal hemorrhage, or they were painfully strangulated with a double canula. Fortunately the day has passed for the total excision of these bodies, except when malignant. Intra or extra-oral this is a dangerous proceeding. In a recent attempt twelve arteries had to be tied; now we are content to remove the projecting portion beyond the lateral half arches of the fauces. When reminded that it is the internal carotid which is exposed in these operations, the value of Dr. Physick's method must be greatly enhanced. Of course the recent modifications of the tonsillotome, some of them quite ingenious, are due to the original forceps containing his concealed blades.

Dr. Physick early advocated putting inflamed joints and diseased bones, as in cases of coxalgia, caries of the spine, etc., in perfect repose, as if in splints.

To him also Monsieur Reybard, then surgeon to the hospital of Lyons, France, declares that the profession is indebted for the first accurate account of cystic or sacculated rectum, which he described in the early part of the present century; Reybard moreover asserts that to Dr. Physick was due the starting point of all improvement which has been made in the treatment of abnormal anus.

It fell to his lot to remove successfully, in one case, a greater number of urinary calculi than has ever been done before or since in Surgery. They amounted to upwards of a thousand, varying in size from a small bean to a bird shot. The patient, who was quite aged, held at the time the office of Chief Justice of the United States, and subsequently resumed his seat on the bench.

A striking proof of Dr. Physick's great influence even in Europe was the fact that, when his nephew, then the Professor of Anatomy in the University of Pennsylvania, published his Elements of Surgery, in two volumes, containing, as was well known, the peculiar views and practice of his uncle, that work, the first of the kind ever issued from the American press, actually became the text-book of Surgery in the University of Edinburgh; which was certainly a high compliment to our distinguished countryman.

Physick's name has ever been the most familiar and favorably known of all American surgeons in Europe; and, in 1825, he was elected a member of the Royal Academy of Medicine of France. He was also an early advocate of conservative Surgery; was a favorite pupil of the renowned John Hunter, the great anatomist, physiologist, and surgeon. As he grew older, Dr. Physick became more chary with instruments, and trusted more to the recuperative powers of nature. Of him, it has been said, that he never spilt a drop of blood uselessly, nor wasted a word in his lectures. With the simplicity of a child, the modesty of a maiden, the industry and integrity of a martyr, he quietly worked out a surgical character which will endure so long as his loved science shall be cultivated.

Intimately connected with the origin, rise, and progress of Surgery in America, were four other professional gentlemen, the contemporaries of Dr. Physick, who were long spared beyond the allotted period of man on earth, as if to illustrate in their lives and characters the benefits of temperance, industry, and benevolence. These were Warren, Mott, Dudley, and Gibson, whose average age was eighty-three years.

There were three distinguished Drs. Warren, of Boston, Mass.; Joseph, the early martyr of American Independence, was the senior, the most talented, most patriotic, most heroic. He it was who fell—musket in hand, having declined the position of commander-in-chief—at Bunker's Hill. Dr. John Warren, his brother, studied medicine under him, and graduated in letters in 1771. He gave the first course of dissections in Boston, which, no doubt, led to the organization of the Medical Department of the well-known Harvard University, in which he was the Professor of Anatomy and Surgery for a quarter of a century. His son, the third of the name, JOHN COLLINS WARREN, was born in 1778, and died in 1856. After the advantages of a thorough education in this country and Europe, he succeeded his father in 1815. He was a liberal contributor to our literature, and author of a work on Tumors, which is said to have shed lustre on our science. His last contribution was published when in his seventy-seventh year. He was the first to operate on a patient put in the anæsthetic condition from ether, and was thereby connected with one of the greatest professional events in the world. Of him Velpeau declared that he first performed the operation for dropsy of the pericardium, for he declared that of all the cases then published, his alone was worthy of full credence; and well he might, for the Warrens were ever the soul of integrity. Mr. George Pollock, in the Medico-Chirurgical Transactions of London for 1838, gives credit to Dr. Warren for first closing the fissure in the vault of the mouth. Of him and his son, J. Mason Warren, the worthy representative of the family, and, we deeply regret now to add, deceased, Sir Wm. Fergusson, the prominent worthy representative of British Surgery, recently declared that in regard to the claim of priority in operations for cleft palate, "the first idea I had of this portion of the operation was obtained from Mason Warren. I deem it but fair," he continues, "to the reputation of that distinguished surgeon to state that I know of no originality before his, and that I look upon all modern claims to such originality as arising either from ignorance or the desire to rob the fair reputation of a name, which in son as in father, will stand for generations among the brightest in Surgery." It is certainly a nice point to decide which is the most honored, he who utters such magnanimous sentiments, or the recipient of so disinterested a compliment.

VALENTINE MOTT, a native of Long Island, near the city of New York, was born in 1785, graduated in 1806, and went immediately to Europe, where he remained pursuing his professional studies three years. On his return home he was elected in rapid succession to the chairs of Surgery in Columbia University, Rutgers Medical College, and the College of Physicians and Surgeons, all in the city of New York. When only twelve years in practice he performed one of the boldest, most original, and difficult operations in Surgery, one too, never attempted before, and yet, to the wonder and astonishment of the profession, the patient survived to the twenty-sixth day, and then died, in our opinion, from imprudence in being permitted to exercise in the hospital grounds. Dr. Mott first tied successfully the common iliac artery, doing this in 1827. He first exsected the clavicle, tying, as he said, over forty arteries, besides the external jugular vein twice, and dissecting out the thoracic duct from the diseased mass. This, which he always considered his most formidable operation, required four hours for its performance. Dr. Gross adds that, as a brilliant and daring operation, it is without a parallel in the

annals of Surgery. Dr. Mott was the first to exsect the inferior maxilla, except its articulations, doing this successfully in 1833. He is said to have tied the carotid fifty-one times, and to have amputated about a thousand limbs. Dr. Gross declares that no surgeon, living or dead, ever tied so many vessels or so successfully, whether for the cure of aneurism, the relief of injury, or arrest of morbid growth. And of him, England's greatest Surgeon, Sir Astley Cooper, generously confessed that Dr. Mott had performed more of the great operations than any man that ever lived. His axiom too, through life, was the liberal one of operating in every case which allowed a rational hope of success, either to improve the patient's appearance or to preserve life. No one probably ever handled an instrument more gracefully, was more nimble fingered, or more skilful than the late Valentine Mott. As an operator, he was probably never surpassed.

Benjamin Winslow Dudley, the great Surgeon of the West, was a native of Virginia, born in 1785, the same year, and graduated the same time that Dr. Mott did, viz., in 1806; he, however, in Philadelphia and the latter in New York. Dudley also spent years in Europe, chiefly under Cline, Abernethy, and Cooper in London, and Larrey, Dubois, and Boyer in Paris. Soon after returning home, he organized the Medical Department of the Transylvania University, at Lexington, Kentucky, in which he occupied the chairs of Anatomy and Surgery, and was ever its ruling spirit. Dr. Dudley was the strenuous advocate of thoroughly preparing for all operations; and taught that if the chylopoetic viscera were properly cared for they would provide for the rest of the system. He gave little medicine, but insisted upon the observance of hygiene, diet, rest, travelling, and even sea-voyages. An Englishman, alluding to Dr. Dudley, is said to have remarked that it had been reserved for a backwoodsman of America to teach how to prepare the patient for a capital operation. He justly claims to have first cured a case—and it was a formidable one too—of intracranial aneurism by due preparation and ligature of the carotid. No one ever did so much with the roller—relying upon it even in fractures—of which he was emphatically the master. He was best known, however, as the lithotomist of the West, if not of America. We unfortunately have no statistics of his operations. If a record of his cases operated upon was ever kept, it must have been lost during the late war. We know that he used the gorget, and he is said to have cut two hundred and twenty-five patients, only six of whom are known to have died. He was truly a surgeon of the conservative school, and was for years the surgical patriarch of the West.

William Gibson was born in Baltimore, Maryland, in 1784, and after receiving a classical education went abroad. He took his medical degree in Edinburgh, and through the friendship of Sir Charles Bell obtained extraordinary advantages. He was at Corunna, Spain, when Sir John Moore fell, and at Waterloo, where he himself was slightly wounded. It was he too who extracted the ball from Gen. Scott, long after the battle at Lundy's Lane. He had met Sir Astley Cooper, Sir Henry Halford, Abernethy, Baron Dupuytren, Napoleon Bonaparte, Velpeau, Lord Byron, and other celebrities. Such was his influence in the profession, that, upon the death of Dr. Dorsey in 1818, Dr. Gibson, though Professor of Surgery in the University of Maryland, actually secured that professorship in the University of Pennsylvania, which was then occupied by the father of

American Surgery, Dr. Physick consenting to take the chair of Anatomy with an adjunct. Dr. Gibson was probably the best lecturer on his branch in the United States; in addition to oral instruction, he illustrated his course by splendid collections of paintings, models, and other appliances. His memory was so retentive that he had been known to repeat three hundred lines of Virgil. He was also a bold and successful operator; he was the first to tie the common iliac artery, for a gunshot wound in the streets of Baltimore, the patient surviving thirteen days. He also performed the Cæsarean operation twice upon the same patient, saving each time the mother and child; an operation since repeated by Drs. William Byrd Page, and John Neill, with like success, so that the good city of Philadelphia has been peculiarly favored in this respect. Much has recently been said—this being the Centennial year—of those who first rocked the cradle of American Liberty; but not a word in commendation of those, who resorted to such extraordinary measures, to keep in motion the little one called into requisition at each accession to her infant population. Alas! for the glory of poor doctors.

In the brief biographical sketches of those to whom we are so much indebted for the present position of Surgery in our country, reference has been made to what they did on the kindred subjects of Aneurism and the Ligation of Large Arteries; and while we may not yet report a successful tying of the aorta, notwithstanding the encouragement implied by finding that vessel occasionally obliterated, and the success by compression reported by Dr. Murray, of Newcastle-upon-Tyne, England, we can, nevertheless, quote what Mr. Erichsen, the well-known author and surgeon, has recently published—"the bold and difficult operation of arresting the circulation through the brachio-cephalic, is one of the most remarkable, and the only one found recorded in the annals of Surgery" —referring to what was done by Dr. Andrew Woods Smyth, of Charity Hospital, New Orleans, Louisiana, the 15th of May, 1864. The patient was a mulatto, aged 22, a steward on a steamer; the tumor, which was of the size of an orange, was developed in four months, after a collision at sea, to which it was attributed. On the 15th of May, 1864, a ligature was applied on the innominate artery, a quarter of an inch below its bifurcation; and one also on the right carotid, an inch above its origin. Pulsation returned at the wrist in forty-eight hours. On the 28th, the ligature came away from the carotid, and the next day, the fourteenth after the operation, hemorrhage occurred to syncope. This recurring the two following days, the wound was filled with small shot. On June 1, the detached ligature was removed from the brachio-cephalic. Hemorrhages still continuing at intervals, on July 9, the right vertebral was tied; being the fifty-third day after the original operation; and to this, the success in the case is fairly attributable. The shot remained in the wound thirty-eight days. The patient now moved to Galveston, Texas, but returned in 1874, ten years afterwards, to New Orleans, with another tumor in the neck causing great pain. Dr. Smyth now detected an aneurism larger than the former one, which the patient said had been developing for about a year. On October 5, 1874, he tied the internal mammary artery in the third intercostal space. Abscesses now began to form under the clavicle and were cautiously opened. The patient again returned to Galveston, and then once more to New Orleans, where he lingered until the 6th of April, 1874. A post-mortem examination

revealed the facts, confirming the history above given of this deeply interesting case.

The patient lived within a few days of ten years after the innominate was tied; enjoyed the best of health, and had gained twenty pounds. In this case Dr. Smyth tied not only the innominate, but the common carotid, vertebral, and internal mammary arteries, and did more to relieve the affection than was ever attempted before in Surgery. This patient lived in a hot, moist climate, and was probably purpuric.

Attempts to ligate the aorta successfully thus far have failed. In this country, Prof. Hunter McGuire, of Richmond, Va., tied it unsuccessfully in 1868; and the next year, Dr. Stokes, of Dublin, Ireland, met with a similar result, though he reached the vessel by an almost bloodless incision through the lumbar region.

Maisonneuve is reported to have tied the vertebral artery. We know that Prof. Willard Parker, of New York, did this in 1863, and as has been noticed, Dr. Smyth, of New Orleans, tied it in 1864. Prof. Warren Stone, of New Orleans, is reported, in a case of gunshot wound of the vertebral artery, to have arrested the hemorrhage by compression with pledgets of lint.

The common carotid, Dr. Gross claims was first secured by Dr. Cogswell, of Hartford, Conn., who in exsecting a scirrhous tumor from the neck in 1803, applied two ligatures to that vessel. Heretofore Sir Astley Cooper's case in 1805, had been considered the first one. In 1875, a surgeon recently from Europe, now Prof. Frothingham, of Ann Arbor, Michigan, boldly laid open a traumatic aneurism of the common carotid, turned out the clots, with a piece of glass, tied both ends of the wounded vessel, as also the internal jugular and lingual veins, and saved his patient. This was certainly a very creditable operation. Dr. Mussey, in 1829, tied both carotids successfully after an interval of twelve days. In Dr. Mott's case the simultaneous application of ligatures to these vessels proved fatal.

Of the branches of the common trunk, the internal and external carotids, the latter is the one which is most frequently tied. Indeed Mr. Bryant in his Practical Surgery, in 1872, declares that, owing to the difficulty of finding the bleeding point, the ligature to the internal branch has been abandoned. Nevertheless it has occasionally been tied by some of our practitioners. In 1845, Dr. J. H. B. McClellan, son of the late Prof. George B. McClellan, founder of the Jefferson Medical College, in removing a portion of the parotid gland found it necessary to ligate this artery; so did Prof. Gurdon Buck, of the New York University, for a deep wound in the parotid region, tie successfully the common and internal carotids; Dr. Stephen Smith, in 1864, secured this vessel after pressure had failed, and he performed a similar operation for sloughing of the tongue; finally, my colleague in the chair of Surgery in the University of Nashville, Dr. William T. Briggs, has the credit of first applying two ligatures, one on each side of a wound which resulted in an aneurism, tying also the common carotid at the same time. This was done in February, 1871. Then again Dr. Sands, Professor of Anatomy in the College of Physicians and Surgeons of New York, without knowing what Dr. Briggs had done, did the same thing in October, 1872, besides securing a lateral wound made in the internal jugular vein.

The method adopted in these latter cases was carrying out the principle of Mr. Guthrie—the application of two ligatures to a wounded artery in contradistinction to the one only insisted upon by John Hunter. This

then is an American illustration of a new principle in tying wounded arteries, which fortunately has occurred in the practice of two of our best anatomists.

The late Prof. Wright Post, of New York, succeeded first with ligature to the left subclavian artery in 1817, a feat which made him quite famous, since some of the most distinguished surgeons of Europe had failed to do this. In 1866, Dr. T. G. Morton also tied the left subclavian, when the upper extremity of that side becoming gangrenous, he amputated it at the shoulder-joint and saved the patient. In two cases of subclavian aneurism, Dr. J. Mason Warren succeeded with ice and direct compression, when the disease was too far advanced for the ligature.

To Dr. Warren Stone, in 1850, is given the credit of first applying a metallic ligature to a human artery, and in 1866, Dr. Claudius H. Mastin, of Mobile, Alabama, applied one successfully to the external iliac. Dr S. W. Gross, son of the professor, has recently proven by numerous experiments how innocuous are ligatures to veins; and the late Dr. Levert, at the suggestion of Dr. Physick, published his thesis, in 1829, proving thus early, the advantage of metallic sutures.

It is difficult to decide who first suggested the ligature to arteries supplying the extremities for affections threatening mortification. Our English friends have generally given us the credit, but it does seem that tying the carotid for internal aneurism, as was done by Dudley, or the femoral for elephantiasis, as was done by Carnochan; the use of pressure to check the redundant supply of blood to a vascular tumor; or even elevating the inflamed part—all apparently illustrate one and the same principle of cutting off the redundant supply of blood.

Arterial compression as an antiphlogistic has long been recognized in the profession. Dr. March published a brochure on the value of compressing the brachial artery in cases of whitlow, a notice of which may be seen in the American Journal of the Medical Sciences, Vol. 18, for 1849. It is there stated that this seemed to be more efficacious than the plan proposed by Mons. Gerdy, of keeping the limb elevated.

Sir James Paget, moreover, declares that the proposition to treat cases of active inflammation threatening gangrene by putting a ligature on the main arterial supply, emanated from the American School of Surgery. In the Lettsomian Lectures on Surgery, published in the London Lancet, Mr. C. H. Maunder, Surgeon to the London Hospital, expressly declares that the operation originated in America; and in Holmes's System of Surgery, Mr. Simon mentions that Henry Campbell, of Augusta, Georgia, then Professor of Anatomy in the New Orleans School of Medicine, and who was an army surgeon during the late war, had even raised the question whether the hand or foot, wrist or ankle, forearm or leg, should ever be amputated for destructive inflammation, specially resulting from traumatic causes, whenever the state of the patient admitted this to be done, without first resorting to previous experimental ligation of the artery supplying the affected region. Dr. Druitt, who contributed the article on Inflammation to the last edition of Cooper's well-known Surgical Dictionary, in 1872, refers, moreover, to Dr. Campbell as the introducer of what he terms the Hunterian ligation of arteries to prevent or relieve destructive inflammation. The operation, first practised by Onderdonk, in 1813, and D. L. Rogers, in 1824, has been revived and systematized by Prof. Campbell, who recommends it as a definite mode of treatment.

Prof. Campbell claims that (1) Compression prevents drainage; liga-

tion prevents blood going to a part. (2) Ligation to prevent inflammation he repudiates as unjustifiable and dangerous, and even liable to produce mortification; while ligation to cure inflammation already existing, he says is invariably safe, and will prevent mortification, or even stop it after it has begun. These distinctions he declares were never brought previously before the profession. He believes that no one before himself ever tied an artery with the distinct view of curing inflammation and preventing gangrene.

One of the most remarkable cases connected with the subject of aneurism, whether considered in reference to its origin, the organ affected, or the extent of the disease and the result of treatment, was reported to the American Medical Association by the late Prof. Mussey, of Cincinnati, when chairman of the Committee on Surgery in 1850. It was that of a mechanic of St. Louis, Missouri, aged 25 years, whose right eye protruded and pulsated; the transverse suture near the external angle of the eyed admitted the tip of a finger, and the functions of both ear and eye of the affected side were no longer performed. After thorough preparation by Dr. Dudley, and ligation of the right common carotid, the patient so completely recovered that he actually resumed the labor of a blacksmith.

Mr. Erichsen acknowledged, in 1851, that to Prof. Carnochan, of New York, was due the credit of recommending a ligature to the femoral artery to cure elephantiasis; when this gave way from the extension of the disease, he tied the external iliac, and finally had to resort to compression on the distal side of the bleeding orifice. Sixteen months after the first operation, the patient was in robust health.

American surgeons have not failed to try compression for the cure of true aneurisms. The late Prof. Jonathan Knight, of New Haven, Connecticut, than whom few ever had a better record, has the credit of first relieving a case of popliteal aneurism by digital compression, the case being published in the Transactions of the American Medical Association for 1848. In the Philadelphia Medical Times for 1875, Dr. R. J. Levis, one of the Surgeons of the Pennsylvania Hospital, published a very creditable case of successful compression for aneurism of the internal iliac. This was effected by means of a simple steel band, having a hollow pad for counter pressure and a convex one with a screw upon the artery. In five and a half hours the current of blood was totally arrested through the tumor; there was some œdema and discoloration, yet the patient fully recovered in thirty-seven days.

Of twenty-three cases of digital compression, comprising a successful one of his own, collated by Dr. S. W. Gross, of Philadelphia, fifteen were reported as cured. In two cases of inguinal aneurism, compression failed.

Within a few days a pamphlet has been received from Walter Reid, M.D., Staff Surgeon Royal Navy, Plymouth, England, in which the author proposes to cure external aneurism by compression in a few hours. Concluding from Cohnheim's experiments that in warm-blooded animals a stasis of circulation may be safely continued for from six to eight hours, he made a successful experiment in a case of popliteal aneurism. Esmarch's elastic bandage was alone applied with the usual pressure of a roller above and below, while the pressure was diminished upon the tumor itself. The proposition certainly deserves further consideration.

In 1860, Dr. John H. Brinton, of Philadelphia, published in the American Journal of the Medical Sciences, an accurate description, with illustrations, of the valve at the termination of the right spermatic vein in the

vena cava ascendens, and its absence on the left side, where the corresponding vein terminates in the renal. Here then is an obvious and satisfactory reason, though it may not be the only one, of the frequency of varicocele on the left side as compared with the right. A suggestion for the treatment of varicocele, originating, if I mistake not, with myself, is the application of animal ligatures to the spermatic cord, excluding, of course, the vas deferens; then the ablation of some four inches square of the scrotum; and the closure of the wound with pin sutures. By this operation, both pathological conditions, the varicose veins and redundant scrotum, are removed.

In the treatment of affections of Bones and Joints, we claim to have made valuable suggestions, if not important additions. An unusual recovery from undoubted fracture at the base of the cranium, which recently occurred on one of our national ships, may deserve brief notice. The sailor was seen to fall from a spar to the main deck, and was taken up insensible; he had stertorous breathing, followed by a copious flow of colored serum from the right ear, estimated at fifty or sixty ounces; and became partially comatose. Brain substance was also detected in the discharges. He, however, gradually improved under treatment, and was returned to duty a little over a month after his fall, though slightly epileptic, and with some little discharge still from the ear.

We find in an early number of the New England Journal of Medicine and Surgery, that Dr. Luke Howe treated a fracture of the inferior extremity by the means now employed, excepting the omission of the sand bags to prevent the rolling of the injured limb; and believed it to be original. His case is reported in 1823, more than half a century ago. In the American Journal of the Medical Sciences for August, 1829, Dr. William C. Daniel, then an eminent practitioner of Savannah, Georgia, described how he applied a silk handkerchief around the ankle and tied it at the sole of the foot, a weight being then attached and passed over a roller for extension. That veteran of American Medical Journalism, Dr. Isaac Hays, says that Dr. Daniel has precedence of all modern claimants for introducing the weight and pulley as a means of extension in treating fractures; for he himself had published two cases thus successfully treated, one in 1819 and the other in 1824. Dr. Hartshorne also, formerly one of the surgeons to the Pennsylvania Hospital, declared in 1869, in the same journal, that the credit of priority in introducing the weight extension in practice was justly due to this gentleman.

To Dr. Gurdon Buck, of New York, credit is given for introducing adhesive plaster to secure extension in the treatment of fractures of the inferior extremity. Prof. Gross, however, in his account of American Surgery, claims this for his preceptor, Dr. Joseph K. Swift, of Easton, Pennsylvania, who employed it as early as 1829.

Dr. William Gibson, of St. Louis, Missouri, devised in 1867, a ring for fractures of the patella; and Dr. P. S. O'Reilly, of the same city, in 1871, described what he calls a new splint for fractures and dislocations of this bone. This consists in an open ring, with a thumb-screw, that it may fit the more accurately; to which a strap extending under the sole of the foot may be added, and also a posterior padded splint for the thigh and leg. This seems the perfection of an apparatus for these injuries.

On the subject of deformities after fractures of the thigh, two of our most distinguished Professors and Surgeons in the Jefferson Medical College hold the position which we also sustain; that a fractured

femur cannot be fully extended to its normal length, nor could it be so retained without impairing its nutrition. They declare that a certain degree of shortening, and perhaps deformity, cannot be prevented, whatever may be the treatment. And it may be added that no measurement whatever can detect the difference in some cases, though one to a limited extent actually exists, as may be verified in a post-mortem examination.

The method of reducing dislocations by manipulation was first systematized and proposed as such by the late Dr. William R. Reid, of Rochester, New York, and published in 1859; though probably first suggested by the late Nathan Smith, of Connecticut. This seems to have created a new era on the subject, notwithstanding that it had occasionally occurred to some practitioners how easily reduction was effected, sometimes even during the examination of the case. Prof. Spence, of Edinburgh, in his Lectures published in 1875–76, calls this the rotatory or circumduction method, and adds, "we generally hear it spoken of as the American method." He also admits that it is undoubtedly to the writings of Drs. Reid and Bigelow, of the United States, that we owe the more general use of the practice. He notices too, specially, the ilio-femoral, or inverted Y ligament, and the different views entertained by Mons. Chassaignac, of Paris, from those expressed by Dr. Bigelow, who was the first to note minutely its functions. Dr. Reid's conclusions regarding dislocations are: (1) That the impediment to reduction is due to the stretch of the muscles, by the malposition of the dislocated bone, and not to their contraction; (2) That in reducing luxations these muscles should be relaxed; (3) That dislocation on the dorsum of the ilium is reduced simply by flexing the leg upon the thigh, and carrying the thigh over the sound one, upwards over the pelvis as high as the umbilicus, and then rotating it.

As is well known to the profession, Prof. Nathan Smith, of New Haven, had taught and published similar views to those of Dr. Reid. The late Prof. Brainard, of Chicago, Illinois, reported, in 1852, the reduction of four cases of dislocation of the head of the femur into the thyroid foramen, with the aid of a billet of wood four inches in diameter, well padded, placed in the perineum as a fulcrum, the displaced limb being then carried as a lever across the sound one.

The substitution of manipulation to reduce dislocation at the hip, is claimed therefore to be American, and in connection with anæsthesia, the great boon to suffering humanity, also introduced by us, to be inestimable.

Old as the world may be, it has been reserved for an American to point out a pathognomonic sign by which a fractured clavicle can always be distinguished from a dislocation at the shoulder joint. Prof. L. A. Dugas, of the Medical College of Augusta, Georgia, asserts that if the fingers of the injured limb can be placed by the patient or surgeon upon the sound shoulder, while the elbow touches the thorax, there can be no dislocation; in other words, he asserts that it is physically impossible to bring the elbow in contact with the sternum, or front of the thorax, if there be a dislocation, and that no other injury of the shoulder-joint can induce this inability. Ample experience has shown this rule to be axiomatic.

The late Prof. Crosby, of New Hampshire, in dislocations at the metacarpo-phalangeal articulation pushed the phalanx backward until it assumed a position perpendicular to the metacarpus; then pressing forward the base of the dislocated finger, reduction was easily effected. Dr. Levis, Surgeon to the Pennsylvania Hospital, suggested a small splint,

having four large gimlet holes bored in it through which tapes are passed to secure a luxated finger or thumb, by which means extension can be effectually made.

As a substitute for the pulley, Dr. Fahnestock, of Pennsylvania, suggested a rope doubled several times upon itself, which by a stick—a walking cane—placed in its centre could be twisted gradually so as to produce extension in dislocations.

In reference to resections and exsections of the bones and joints, our surgeons have been active and ingenious. As early as November, 1826, Dr. John Rhea Barton, then one of the surgeons of the Pennsylvania Hospital, sawed through the femur just between the trochanters, and then straightened the limb, which became so useful that the patient went out gunning and actually brought home his own game; owing, however, to his habits, those of a common sailor, he did not derive the full benefit expected from the operation; but a similar one, in which, however, a disk of bone was removed, performed by Dr. J. Kearney Rogers, of New York, in 1830, resulted by gentle manipulation in the formation of an artificial joint, and in an excellent recovery: good success has attended other cases similarly treated by our practitioners. Mr. Erichsen declares that the first operation for osseous angular anchylosis was performed by Dr. Barton. He also asserts that, in 1837, Dr. Mussey excised the whole of the scapula and clavicle for an enormous osteo-sarcoma, the patient being in good health fifteen years afterwards. These successes no doubt induced others to enter the new field of investigation, and resulted in Dr. Brainard, then Professor in the Rush Medical College, Chicago, Illinois, submitting, in 1854, to the American Medical Association, an essay on a new method of treating ununited fractures, and certain deformities of the osseous system, which secured the prize for that year. The main feature in Dr. Brainard's method was that by making perforations in the osseous structure with drills, and then waiting for the softening process of inflammation, almost any bone, or anchylosed joint, might be straightened, broken up, or the deformity relieved. Barton, Brainard, and Buck, were undoubtedly the pioneers in correcting deformity and restoring to usefulness, limbs, which before their day were considered hopelessly useless, or were sacrificed by amputation.

The first resection of the inferior maxilla was performed in what was then known as the back-woods of America, and this too without known precedence, or even professional counsel or assistance. The case is admitted by Mr. South, who translated Chelius's Surgery, Drs. Mott, Gibson, Gross, and others. The operator was William H. Deadrick, then of Rogersville, East Tennessee, who in February, 1810, exsected about three inches of the lower jaw, including the whole of its circumference and one of its angles, from a boy, fourteen years old, who recovered and was alive years afterwards. Dr. Carnochan, of New York, is believed to have first disarticulated this bone in its entirety in the Emigrants' Hospital, of New York, in 1851; and this was again done the next year, by Prof. Wedderburn, then in the Medical College at New Orleans.

The late Prof. Horatio G. Jameson, of Baltimore, claimed for his country the honor of having led the way in resections of the superior maxilla. Dr. Gross admits that the first severe and difficult operation of this kind was performed by him successfully in 1829, by removing nearly the entire bone on one side.

The removal of the clavicle, or a portion of it, was probably first attempted by Dr. Charles McCreary, of Hartford, Kentucky, and was

reported by James H. Johnson, in the Medical Journal then published in New Orleans, in 1850. In his System of Surgery, Dr. Gross mentions that the operation was performed in 1815, on a boy who survived long afterwards.

As early as 1853, Dr. Compton, of New Orleans, exsected the entire ulna and all of the radius, except its lower extremity, in a patient fifteen years old, who made an excellent recovery.

In 1843 Josiah C. Nott, then Professor of Surgery in the Mobile Medical College, excised two segments of the coccyx, for neuralgia, in a lady after twenty-five years of great suffering. The case, first published in the New Orleans Medical Journal for 1844, was copied into the American Journal of the Medical Sciences, and Prof. T. Gaillard Thomas has added that this was fifteen years before a similar operation was performed by the late Sir James Y. Simpson.

Prof. Lewis A. Sayre, of New York, reports that, up to January, 1876, he had exsected the head of the femur fifty-one times, with a mortality of only twenty; eight of these fatal cases too had recovered from the operation. He removed also portions of the acetabulum in some of these instances. At the late meeting of the American Medical Association in Philadelphia, he introduced a little patient, suspending him by the shoulders and head; plaster of Paris bandages were then applied, and in a few minutes the little boy walked about the room, though he had not done so for months before.

In connection with affections of bones and joints, did time permit, there might be noticed what has been done here in Kyllosis and Orthopædy. Dr. James A. Dickson, of North Carolina, is believed to have first performed tenotomy by dividing the tendo Achillis in 1835, followed by Dr. D. L. Rogers, of New York, in 1845. Then came Dr. Detmold, a pupil of Stromeyer, who in 1837 settled in New York, where he introduced myotomy. Dr. Mott, however, founded the first Orthopædic Institution in America. In 1844, Dr. Henry J. Bigelow, of Boston, Massachusetts, obtained the Boylston prize for that year for his work on Orthopædy. Dr. Sayre, however, has done more on this subject than any other American. His work just published is undoubtedly the best ever issued from the press. He has called particular attention to genital irritation, even in very young children, in connection with deformity. He gives special credit to Mr. Barwell, of London, and Dr. H. G. Davis, of New York, for devising apparatus for extension while the little patients exercise in the open air; and has himself introduced a new method of doing this by plasters, elastic cords, or artificial muscles, as they are called. For contracted limbs and congenital deformity much is being done here by early attention, so as to prevent development in unnatural positions, by gradual or forced flexion and extension under ether, electricity, etc., before resorting to tenotomy or myotomy.

In the Compendium of Practical Surgery, published in 1851 by Bérard, Denonvilliers, and Gosselin, of Paris, in referring to a paper written by Dr. M. Smith, son of the celebrated Dr. Nathan Smith, commenting on incisions of the periosteum and trephining of bones in suppurative inflammation, is found a compliment to the heroic measures proposed by the Americans.

In reference to the Genito-urinary Organs, we refer first to the case of Dr. Charles L. Stoddard, of Wisconsin, who is reported to have exsected the kidney successfully in 1861, eight years previous to the operation of

Prof. Simon, of Heidelberg, who operated in 1869. In 1870 Prof. Gilmore, of the Mobile Medical College, successfully cut out an atrophied kidney from a colored woman, then five months pregnant, who, nevertheless, went to her full term, and was safely delivered of a living child.

Our early surgeons performed almost exclusively the lateral operation for urinary calculus, and almost as exclusively employed the gorget—an instrument of which it can happily be said *requiescat in pace.*

Ribes, of Paris, first described accurately the bilateral operation for stone in the bladder. Dupuytren, however, gave it character by proving its advantages to be easy and more direct access to the bladder, and that the prostate is cut in its central portion, and in double the extent of the section in the lateral operation, without endangering nerves, vessels, or other important structures. Dr. Ashmead, of Philadelphia, in 1834, first performed the bilateral operation in the United States.

Mr. Erichsen asserts that Civiale recommended a combination of the median and bilateral operations, for in this way, he declares, the chief objections to both are removed. The medio-bilateral is gaining ground as an operation for urinary calculus.

As is well known, when Mr. Erichsen, among others, denied the possibility of the intromission of foreign bodies below the vocal cords, Dr. Horace Green passed a tube through the rima glottidis some inches into the trachea, and then withdrawing the stilet, directed the patient to close his lips and blow through the canula. This he did several times, even so forcibly as to extinguish a candle. Sponging below the vocal cords was first done in October, 1854, by the same gentleman.

The case reported by Profs. Crosby and Peaslee, of New Hampshire, of a sponge one inch and three-quarters in breadth and fifteen-sixteenths of an inch in thickness, passing the rima glottidis, in a patient aged forty-five, on July 23, 1850, and who lived fifty-four hours, ought surely to have convinced every one of the possibility of at least introducing sponge-probangs into the larynx.

In 1844, Dr. Charles Hall, of Burlington, Connecticut, removed, after tracheotomy, a piece of pipe-stem by means of a probe, which fortunately entered the hollow or canal of the pipe-stem and stuck fast. This certainly was a fortunate hit. Mr. Liston once extracted a piece of sponge from the right bronchus of an adult; and Mr. Dickin, in 1832, a bell button from the right bronchus of a child eight years old.

Mr. Spence, Professor of Surgery in the University of Edinburgh, succeeded, in June, 1862, in extracting, by tracheotomy, the inner portion of a tracheal tube which had lodged in the bronchus, and concluded that it was the first and only instance of the kind thus relieved. A child, however, was brought from Alabama in May, 1853, to Augusta, Georgia, where, after the trachea had been opened, a four-penny nail was removed from the left bronchus with a pair of dressing forceps lengthened in the blades.

American surgeons present a creditable report on amputations. Statistics on the subject, whether derived from hospital records or army reports, or more especially from private practice, sustain this position. Much, no doubt, is due to our open climate, sunny country, cleanly habits, good nourishment, and free exercise. Even in regard to the dreadful operation of amputation at the hip-joint, it is probable that the second successful case, if not the very first ever performed, was that of Dr. Walter

Brashear, of Bardstown, Kentucky. This was done in August, 1806, on a youth of seventeen years, who survived long after it. His method was the circular, as if for the upper third of the thigh; and, after securing the arteries, then the head of the bone was disarticulated through a long incision over the trochanter major. May not this prove to be the best method for this amputation? The case of Perault, of St. Maure, France, in 1773, was only the semblance of an amputation, since the limb had been destroyed by mortification up to the hip.

Mr. Erichsen, Baron Larrey the second, and M. Legouest, of the French army, declared most emphatically that there had not been a case of recovery from primary hip-joint amputation recorded in military surgery previous to our late war. In the Schleswig-Holstein, French, German, and Italian wars, not a case survived, whether operated upon by German, English, French, Italian, or Russian surgeons; whereas, during the late war between the States, some three or four were reported as successful, though subsequently this number was reduced, because, on account of the difficulty in the condition of the country, after our gigantic internecine war, these cases could not be accurately determined. We may judge, however, of the impression of our success in operations at the hip-joint in Europe, when the Surgeon-General of the Prussian army, the distinguished Dr. Von Langenbeck, declared that, but for these operations, it might be questioned if immediate amputations and resections at the hip should not be hereafter prohibited.

In the New York Journal of Medicine, for 1852, it is stated that up to that date there had been on the Continent of Europe thirty-five amputations at the hip, with fourteen recoveries, or forty per cent.; in England twenty-five, with eleven recoveries, or forty-four per cent.; and in the United States eleven, with eight recoveries, or seventy-three per cent.

In civil practice, we have the recent remarkable case of Dr. Jerome Sands, of Portchester, New York, who, without waiting for reaction after the injury by a passing train, performed hip-joint amputation by antero-posterior flaps, on a boy eleven years old. The administration of ether, performing operation, and dressing wound, all consumed only three hours. Prof. Spence, of Edinburgh, under similar circumstances, waited several hours before he operated; his case too, was a success, and it may be the first and only one of the kind in Europe. In Philadelphia, where surgery has been so successfully practised, two of her Professors in one College, Drs. Gross and Pancoast, have each performed two amputations at this articulation, and saved the four patients. Yet this is the operation, it will be remembered, of which the great English military surgeon Hennen, asserted, only fifty years ago, that there was not one in a thousand who would not prefer instant death to the attempt.

No one can be expected to do justice to so prolific a subject as the history of American Surgery, in the brief space allowed the occasion. An enumeration of our contributions to this department of medicine would alone require a volume. Time will permit now only a brief summary of some suggestions or improvements not yet noticed.

The extensive use of silver wire in surgery and gynæcology is undoubtedly due to Dr. J. Marion Sims. This is acknowledged in Holmes's Surgery. To him also is given the credit of publishing the first work ever issued on Uterine Surgery in the English language.

Paracentesis thoracis was made a safe operation by Drs. Bowditch

and Wyman, of Boston, before the introduction of Dieulafoy's aspirateur.

Dr. A. L. Pierson, of Salem, Massachusetts, was the first to operate for hare-lip with scissors and sutures, within six to twelve hours after birth.

Prof. Alex. H. Stevens first suggested the important principles to be observed in exsecting tumors, viz., by the first incision to expose fairly the morbid growth, and secondly to remove it and nothing more.

The œsophagus forceps of Dr. Bond, of Philadelphia, are so constructed that, by narrow bevelled edges, a pin or fish-bone can be removed without pinching the mucous coat.

Of Dr. Sayre's vertebrated probe, Mr. Erichsen declares that it is a most ingenious and valuable one, by accommodating itself to the tortuosities of a canal or sinus.

Dr. Levis, of the Pennsylvania Hospital, recommended pure carbolic acid liquefied, as a local anæsthetic, before using the actual cautery, and the late Prof. Josiah C. Nott, of Mobile, declared that this same agent in carbuncle was antiseptic, escharotic and anæsthetic.

Prof. Joseph Jones, of the University of Louisiana, New Orleans, one of the most indefatigable laborers in the profession, after a most thorough examination of the important subject of traumatic tetanus, concludes that the remedial agents most to be relied upon, are chloral hydrate, Calabar bean, chloroform, sulphuric ether, cannabis Indica, tobacco, bromide of potassium, and opium. He also suggests that important advances will be made in the therapeutics of this affection, if the attention of the entire profession can be concentrated on a few remedial agents, as chloral hydrate, Calabar bean, and bromide of potassium. In regard to the prevalence of this terrible affection, the census of the United States for 1850 gave six cases for the six New England States, while for Louisiana alone there had been two hundred and fifteen.

Prof. F. H. Hamilton, of Bellevue Hospital, New York, is the author of a well-known Treatise on Fractures and Dislocations, which has reached its fifth edition. He has recently issued a System of General Surgery, of about one thousand pages, with illustrations; and has also published a Treatise on Military Surgery and Hygiene. During the war, he held a high rank, and has long been known as one of our ablest surgeons.

The Principles and Practice of Surgery, by John Ashhurst, Jr., M.D., issued by Henry C. Lea, Philadelphia, 1871, a volume of a thousand pages, containing five hundred and thirty illustrations, has probably done more than any other publication to announce what Americans have done for surgery.

The founder of the Jefferson Medical College, Prof. George McClellan, reported, long ago, eleven excisions of the parotid gland with only one fatal case.

Prof. Van Buren, M.D., of Bellevue Hospital, recommended the French method of relieving anal fissure, by sudden dilatation from within outward with the thumbs, so as to rupture or tear open the sphincter muscles.

The British and Foreign Medico-Chirurgical Review stated in 1870 that, in plastic operations on the face, and in closing of wounds and unnatural openings in the urinary organs and parts of generation, Americans must have the position of precedence.

Another surgeon, Professor Gouley, of New York, has distinguished himself in external urethrotomy without a guide, and in relieving strictures.

Dr. John T. Hodgen, Professor of Surgery in the St. Louis Medical

College, proposed a few years ago the removal of calculi lodged in the urethra, by passing a double wire concealed in a catheter, and expanding it after its introduction into that canal.

Prof. Henry J. Bigelow has recently published an article on "The true Neck of the Femur," another on "Exstrophy of the Bladder," and a third on "Turbinated Corpora Cavernosa."

Dr. Addinell Hewson, Surgeon to the Pennsylvania Hospital, found a mortality, after amputations performed with an ascending barometer, of about eleven per cent.; when it was stationary, some twenty; and when descending, amounting to twenty-eight per cent. This certainly deserves investigation.

In proof of the industry exhibited, and of the contributions made by Americans to Medical Science, a long catalogue of periodicals, numerous monographs, and extensive systems in the three practical departments of the profession might be enumerated. One of these, on Surgery alone, has reached the fifth edition, contains fourteen hundred engravings, and requires a text of more than two thousand pages in small type; being equivalent to more than half a dozen volumes of ordinary size. Then there are some forty Journals devoted to medical science, from the weekly to the quarterly, containing reports of cases, lectures, movements in the profession, etc.

We can point, too, to the admirable publications issued from the office of the Surgeon-General U. S. A., pronounced to be incomparably the most minute, comprehensive, and valuable ever issued from the press. And, as evidence of the industry and efficiency of our corps of Surgeons, it is said in the official reports of the late war between the States, that the mortality in the medical staff was greater than in any other.

The commendations from foreign sources respecting these publications, have been most gratifying to our national pride. The Medical Inspector of the French army, and director of the school for the Medical Staff of that army, Mons. Sédillot, wrote, in 1866, that American Surgery had proved itself equal to cope with the exigencies of a war of incomparable magnitude; surgeons everywhere, said he, were proud of the marvels accomplished in science and self-devotedness.

In Circular No. 6, are classified 87,822 wounds and injuries, and 17,125 operations. These reports have been translated into the German, French, and Italian languages. The Director-General of the British Medical Department returned thanks for the gift of a work so replete with interest of the highest professional value. Sir Wm. Fergusson said in the fifth edition of his standard work on Surgery, that modern surgery owed much to our American brethren—referring to conservatism, which he says was signally displayed both in the United States Army, and by their gallant contemporaries in the Confederate service. Baron Von Haurowt, chief Surgeon of the Russian Marine, in a report for 1867, after an official inspection of the medical institutions of this country, speaks of the Army Medical Museum, at Washington, as the most valuable collection of the kind in existence.

In an address to the students of St. Thomas's Hospital, London, Oct. 1874, Mr. McCormac said, no European nation, probably, can point to such a monument of industry, or so great a mass of valuable material, carefully preserved and digested, as the records of the Medical Department of the U. S. Army. It is, he continues, an undertaking simply gigantic, reflecting credit on the government that originated, and the men who carried it out. Such records, he says, are of the utmost value

both to the military and civil service. No less than fourteen foreign medical journals noticed our Army medical reports.

In 1875, Dr. Crothers, of Albany, New York, stated that Dr. Swinburne's attachments for extension and counter-extension were being introduced into the French army, with the American pattern and minutiæ for the battle-field. Dr. Swinburne, himself, formerly Port Physician of New York, while travelling in Europe in 1870–71, by request took charge of a hospital, and he and Dr. Evans, Dentist to the French Emperor, received the Cross of Honor for services rendered. Dr. Monsereau declared before the Faculty of Paris, that the American Ambulance was the best of all.

In the Prussian Service, our ambulance was also adopted. So again, Mons. Sarcey, who wrote the "Siege of Paris," announced the superiority of this method of treating the wounded on the battle-field. It was freely confessed that American Surgeons had done more for Military Surgery than the ordinary experience of a century, and that never before was the business of life-saving done more thoroughly and successfully than during our great war.

The discovery of the circulation of the blood in 1628, and the introduction of vaccination in 1796, were the significant events of the past two centuries in our profession. That of the present one will, in all probability, prove to be the crowning glory of American Surgery. For it is that which Poets and Philosophers, Philanthropists and Physicians, and the Humane of all ages, had sought for in vain for six thousand years. The search had been for that agent which could suspend consciousness and obtund sensibility, so that the most painful manipulations might be made, or capital operations performed, with little or no risk to life. It has been reserved for American Surgery to teach the world how to prevent or relieve human suffering. God in his mercy has condescended to teach us how to relieve pain. We can now say to the agonized mother, Awake! behold your babe; to the tetanic limb, Peace! be still.

Well has it been said that no imagination can conceive and no tongue express, the accumulated woe that anæsthesia has assuaged, and is yet destined to prevent or relieve.

Fifty years ago, there were probably not a half-dozen Americans known abroad as Surgeons. As early, however, as 1830, Dr. Reese, in preparing an American Edition of Cooper's Surgical Dictionary, introduced no less than one hundred and nine American contributions to it; and Mr. Cooper, himself, soon after, publicly expressed his regret for not having noticed what we had done in this department of medicine; admitting, too, that we had performed operations never attempted in Europe, and had led the way by our splendid achievements in operative Surgery, and demonstrated their practicability and success. The hour assigned me for presenting what we have done in Surgery, during the past century, especially its latter half, has expired; the result, however imperfect, is before you. Time, if nothing else, has prevented even the naming of all that is worthy of special mention. I trust, however, that quite enough has been shown to warrant us in committing the interests of our time-honored calling, the noblest of earth, to our successors of a second centennial, in the full persuasion that all its interests, its usefulness, its honor, and its dignity, will be fully sustained.

ADDRESS ON MEDICAL BIOGRAPHY.

BY

J. M. TONER, M.D.,

OF WASHINGTON, D. C.

GENTLEMEN OF THE CENTENNIAL INTERNATIONAL MEDICAL CONGRESS:

I APPEAR before you to discharge the duty assigned me of preparing a biographical retrospect of the medical profession of the United States during the centennial period just past. Though apparently an easy task, I cannot approach it without hesitation. Apart from the feelings of diffidence, which under any circumstance this occasion and this audience must inspire, I am fully aware of the caution with which the office of the biographer should be assumed, and that his best efforts are never above criticism.

It is admitted that the measure and the character of the renown which attaches to the hero is, in a great degree, qualified by the fitness of the chronicler who undertakes to record and perpetuate his achievements. With what intimate knowledge and forecast, then, should even the most ready pen essay the work of writing the life of the good and great; when, through natural inability for the task, or want of care, the noblest actions may be placed in a false light, obscuring what should be displayed, or obtruding defects that the mantle of prudence and charity should cover! Conscious of the many difficulties and the very brief time allotted to the reading of this discourse, I shall confine myself to the narration of a few simple facts in the lives of the more illustrious, and to a record of the names of physicians who attained distinction during the century, and I trust that this limitation may be some excuse for the dryness which must necessarily characterize such details.

In glancing over the period to be embraced in this retrospect, I am struck by the paucity of really striking events which have influenced the practice of medicine, and which have left special marks at the end of the first century of our national existence.

Wars have generally been promotive of medical science, and our profession was no doubt much benefited by the contest for Independence. For the first quarter of a century after this armed struggle, the leading physicians and surgeons were those who had served in the army.[1] The most notable event of this period was the occurrence of epidemics of yellow fever, which appeared in the summers of 1793 and 1798 in nearly all our Atlantic cities. This disease tested the courage and taxed the energies and best skill of the profession, and prompted the more eminent

[1] The following are the names of the leading practitioners in each State who served during the Revolutionary War: Connecticut, Aneas Munson; Delaware, James Tilton; Georgia, Lyman Hall; Maryland, John Archer; Massachusetts, John Warren; New Hampshire, Josiah Bartlett; New Jersey, William Burnett; New York, Charles McKnight; North Carolina, Charles Harris; Pennsylvania. Benjamin Rush; Rhode Island, Isaac Senter; South Carolina, Peter Fayssoux; Virginia, James McClurg.

to reduce their observations to writing, and to have them published, either in defence of their practice, or for the laudable purpose of making contributions to medical science. To us of the present day, it is an agreeable surprise to find that there were then so many medical men of literary ability[1] in our country.

The second quarter of the centennial period was distinguished by the introduction of vaccination, the occurrence of spotted fever, and the war of 1812. All of these were events which stimulated the profession to more extended studies, and became incentives to authorship; this was especially true of the disease known as spotted fever.[2] The war of 1812 proved to be another great school of experience, although it was not fruitful in medical reports or publications. The aspirations which it aroused in the profession, however, gave an impetus to the establishment of medical periodicals, and to the founding of medical colleges[3] and hospitals.

In following out the plan of dividing the century of our independence into quarters, the third may be marked as noted for the discovery of anæsthesia, the epidemics of Asiatic cholera of 1832 and 1848, and the war with Mexico, as well as the discovery and the application of many new and improved methods of physical exploration in the search of disease. These aids to diagnosis encouraged more than ever the recording of clinical observations and their publication. Medical journals multiplied,[4] and new medical colleges were founded in most of the States.[5]

The last quarter, which has just closed, is specially distinguished by the vast experience of the late war, which was a great school, and which

[1] In my own library I find pamphlets on the epidemics of yellow fever of 1793, and 1798 published before 1800, by the following authors: Dr. J. S. Addoms, Dr. Richard Bayley; Dr. Thaddeus Brown, Dr. C. Caldwell, Mathew Carey, Dr. Isaac Cathrall, Dr. W. G. Chadwell, Dr. Colin Chisholm, Dr. Thomas Condic. Dr. William Currie, Dr. John Beale Davidge, Dr. M. S. Davis, Dr. Jean Deveze, Dr. Richard Folwell, Dr. James Hardie, Dr. J. Henry C. Helmuth, Dr. Charles Holt, Dr. Alexander Hosack, Dr. William Linn, W. Marshall, Dr. D. Nassy, Dr. Pascalis, Dr. J. Patterson. Dr. Benjamin Rush, Dr. Charles Scot, Dr. James Tytler, Dr. Washington Watts, Dr. Noah Webster, and Dr. Nathaniel Weeks. There are also many reports by committees and boards of health, besides numerous articles on the subject in the "New York Medical Repository."

[2] The following are a few of the most noted writers on spotted fever: Elisha North, Job Wilson, Thomas Miner, William Tully, L. Danielson and E. Mann, Elijah Lyman, Samuel Woodward, Abraham Haskell, Mason Spooner and Jacob Holmes, John Bestor, Q. Fiske, and G. Williamson.

[3] In 1800, there were in the United States but four medical colleges organized and giving instruction, viz.: University of Pennsylvania, Pa.; Columbia College, N. Y.; Harvard College, Mass.; and Dartmouth College, N. H. The number of medical colleges fully organized and giving instructions in the United States in 1825, was eighteen, viz.: University of Pennsylvania, Pa.; College of Physicians and Surgeons, N. Y.; Harvard College, Mass.; Dartmouth College, N. H.; University of Maryland, Md.; College of Physicians and Surgeons Western N. Y., N. Y.; Yale College, Conn.; Medical College of Ohio, Ohio; Vermont Academy of Medicine, Vt.; Transylvania University, Ky.; Brown University, R. I.; Medical School of Maine, Me.; University of Vermont, Vt.; Berkshire Medical College, Mass.; Medical College, S. C.; Jefferson Medical College, Pa.; Columbian Medical College, D. C.; University of Virginia, Va.

[4] It has been ascertained that about two hundred medical journals have been started in the interest of regular medicine in the United States within the centennial period. Of this number, about thirty are now being published. From an estimate, based on pretty good data, I am persuaded that something over seven hundred medical men have been engaged as editors and assistant editors of journals within this period. Medical editors, as a class, are ready writers, well informed, enterprising, and progressive in their profession. The influence of medical journal literature is elevating, and encourages study and the reporting of cases.

[5] At the end of the third quarter, 1850, the United States census gave a list of thirty-seven medical colleges fully organized and giving instruction.

has benefited the medical profession of the whole country;[1] by the extended use of anæsthesia in painful surgical operations; by the increase of scientific means for exact diagnosis, and the introduction of new and potent remedies and modes of administration; and by the founding of hospitals and medical colleges in nearly all the large cities.[2]

It is from the professional men who labored not only in these more notable scenes, but from the whole profession who practised during this period, that I shall select for comment those who acquired honorable distinction among their contemporaries. It is well known to you that owing to the peculiar condition and growth of our country, from thirteen Colonies to forty-nine States and Territories during the century, it is difficult to so treat the subject as to be entirely impartial, and not to neglect the claims of any section of the country, old or new.

I will first speak of the medical men of the United States who have by their discoveries, writings, or special skill and devotion to their professon, won national fame, and then of those who have attained distinction within the several States. Having an earnest desire to make the address acceptable to this Congress, and for the sake of making it worthy of the occasion, I have collected formal biographies of one hundred of the most eminent medical men of the United States for the century. These sketches have been prepared at my request by physicians of note in possession of the requisite data.[3]

We know that greatness in any avocation, and particularly in the medical profession, is not a birthright, nor can it be thrust upon the undeserving. A kind of popular transitory applause may be achieved without merit, but only those who have done something to advance medical knowledge or to improve the methods of cure, will live in history. The discoverer or the expounder of a new truth, the recorder of an additional fact or a hitherto unobserved symptom, or of an improved procedure in surgery or in the treatment of disease, deserves and will secure a more enduring place in history than he who has gained great popularity or the largest fortune. The qualities and acquirements and the degree of these which can make a medical man illustrious either in his day or in history, I shall not attempt to define. The talent differs in kind and degree that attains eminence in different periods of time, and in the city as compared with the rural districts, in the surgeon[4] as compared with the physician,[5] and in the writer[6] as compared with the

[1] The late war did for us what the wars of Europe in 1848 and 1856 did there. It improved surgery much, and developed pathology wonderfully, brought hygiene into active exercise, improved the treatment of bone injuries by exsection and resection, and the treatment of wounded joints. The conservative treatment of limbs, the postponement of the period of operation, and the improvement in hospital construction and treatment, mark this period not less than the actual number of operations performed by the extended use of anæsthetics.

[2] The close of the last quarter of the centennial period records sixty-five medical colleges, not including dental schools or colleges of pharmacy.

[3] [The biographies referred to in the text, are necessarily omitted for want of space.—EDITOR.]

[4] Professor Samuel D. Gross, in the "Century of American Medicine," published in the American Journal of Medical Sciences, names nearly three hundred American surgeons, who, by their operations and reported cases, have won an enduring place in the literature of the profession.

[5] Dr. T. Gaillard Thomas, in the "Century of American Medicine," published in the American Journal of Medical Sciences, names nearly one hundred and thirty American physicians who have won distinction in obstetrical practice and gynæcological surgery.

[6] Professor S. D. Gross, in his Introductory Lecture entitled "History of American Medical Literature," names nearly three hundred medical authors for the century. From an

teacher.[1] But that there is a something in talent or character which commands success, and that this element stands in the relation of cause to effect, is generally conceded. Even when an elevated standard of professional ability has been adopted, I am embarrassed not only by the difficulty of selection, but by the superabundance of good material.

The names here presented as having won pre-eminence in the medical profession of America, have acquired their distinction chiefly by the possession of high natural endowments and of good education and medical knowledge, with the exercise of unceasing study, and devotion to professional duty. My study is too limited to assume that names not included may not be equally deserving.

The natural ability, habits of industry and systematic study, and scientific knowledge of Dr. Benjamin Rush, added to his acquaintance with men and public affairs, easily place him at the head of the list of the eminent medical men of the century. His professional skill, high moral and benevolent character, and frequent participation in the affairs of his country, rendered him popular with the profession and endeared him to the people. His fame has suffered but little by the lapse of time. His writings are numerous and valuable. (b. December 24, 1745; d. April 19, 1813.) But as the subject of medical literature has been assigned to an abler pen, I shall leave that branch entirely to him.[2]

Dr. Valentine Mott, by his daring and brilliant operations in surgery, held for many years the front rank. He had the physical and mental endowments, as well as scientific acquirements, application, and professional training, essential to a great surgeon. There is scarcely an operation, however hazardous or delicate, that he did not perform with consummate skill and success. His genius, too, was equal to devising new operations and important surgical procedures, and undertaking and executing some operations which before his day were passed over as too formidable to be attempted. He was scarcely less eminent as a writer and teacher than as a surgeon, and no American name is better known to the profession throughout the world. (b. August 1785; d. April 26, 1865.)

Dr. Philip Syng Physick was a surgeon of rare ability, self-possession, and fortitude. As was usual, when he commenced practice, he attended to the general business of physician and surgeon, but as early as 1794 he was appointed one of the surgeons to the Pennsylvania Hospital, and in 1805 Professor of Surgery in the University of Pennsylvania. He always carefully prepared his lectures, and was therefore particularly impressive, for he had thought over and mastered the subjects he presented. He was the author of so many improvements in the department

estimate I have made on this subject, I conclude that there are some four hundred authors who have published works, which from their size are entitled to be termed books. If we include pamphlets, it is probable that there are over fifteen hundred medical authors

[1] From a computation which I have made of the teachers of medicine in our country, for the century, I am inclined to think that the list will include nearly two thousand names.

[2] Professor L. P. Yandell, of Kentucky, has been designated to deliver the address on "American Medical Literature" for the centennial of our national existence, and to Prof. N. S. Davis, of Illinois, has been given the task of preparing an address on "American Medical Education" for the same period. To Prof. Austin Flint, has been assigned the duty of preparing a history of medicine in our country for the hundred years just past. A careful regard for the field of labor given to each of these essayists, has made me solicitous not to traverse their province, but to adhere strictly to biographical detail at the risk of being tiresome.

of surgery that he was justly entitled to the appellation given him of "The Father of American Surgery." His influence upon practice is felt to the present day. (b. July 7, 1768; d. Dec. 15, 1837.)

Dr. John Warren was an eminent physician and surgeon, and medical teacher. He acquired experience and reputation in the hospitals of the Revolution. While attached to the hospital at Boston, in 1782, he founded the Medical Department of Harvard College, in which he was Professor of Anatomy and Surgery. He was a man of great industry, and enthusiastically attached to his profession, and was during his lifetime the leading surgeon of New England. His genius and aptitude for this branch of the profession has continued to show itself in his descendants. (b. July 27, 1753; d. April 4, 1815.)

Dr. Daniel Drake possessed wonderful powers of original observation, and was the most indefatigable worker for the accumulation of knowledge and the elevation of the profession, that our country has produced. He was the founder of medical colleges in the West, and a writer and teacher of great force and ability. His systematic inquiries into the causes of disease are models worthy of study. The Doctor's valuable labors are certain to be appreciated in the future. (b. Oct. 20, 1785; d. Nov. 6, 1852.)

Dr. John Collins Warren was one of the founders of the Massachusetts General Hospital, and the surgeon in daily attendance to the time of his death. He was the first to use ether, and did much to hasten its introduction into general use in surgery. He was a brilliant operator, popular as a lecturer, and wrote on a great variety of subjects, in all of which he showed his exact knowledge and extensive scientific acquirements. (b. 1st Aug. 1778; d. May 4, 1856.)

Dr. Nathan Smith was a man of extraordinary natural endowments. His ability to acquire knowledge, his industry, perseverance, and success under almost insurmountable difficulties, have rarely been equalled. His founding of the Medical Department of Dartmouth College, and his teaching, by himself, for ten years, all the usual branches, show the character of the man. He was an admirable anatomist, a bold and successful surgeon, and a good general practitioner. By his teachings he did much to advance medicine. (b. Sept. 30, 1762; d. Jan. 26, 1829.)

Dr. Reuben Dimond Mussey was a distinguished surgeon and good general practitioner. His experiments on cutaneous absorption would have of themselves entitled him to a high rank, had he not become still more eminent as a surgeon. For daring and success, some of his capital operations have never been excelled. He was also a popular and successful teacher of surgery. The esteem in which he was held by the profession may be inferred from his election to the presidency of the American Medical Association. (b. June 23, 1780; d. June 21, 1866.)

Dr. James Jackson was a noted physician and author. He was one of the founders of the Massachusetts General Hospital. His great skill in diagnosis, and his eminent success in the treatment of disease, led to his appointment to the professorship of Theory and Practice in Harvard College. His observations, teaching, and writings, almost mark an epoch in medicine in this country. His professional life and labors were great lessons to the profession of high and honorable principles. (b. Oct. 3, 1777; d. Aug. 27, 1867.)

Dr. Nathaniel Chapman was a learned and eminent physician, and teacher of medicine. His special qualifications and success as a physician speedily attracted attention, so that his business was very large and

responsible. He was for a long time a professor in the University of Pennsylvania, and was in some respects the most popular lecturer with students ever resident in that great centre of medical education. His writings have had much influence over the medical opinions of his time. He was President of the American Philosophical Society, and the second President of the American Medical Association. (b. May 28, 1780; d. Jan. 1, 1853.)

Dr. Theodoric R. Beck was a prominent physician, author, and teacher. He was particularly notable for his literary and scientific attainments, power of classification, and scope of studies. Professor in several colleges, he filled one of the first chairs of medical jurisprudence established in this country. His work on this science would of itself entitle him to rank with the most cultivated medical men of the Union, and has been for years the class-book in foreign schools of medicine. (b. Aug. 11, 1791; d. Nov. 19, 1855.)

Dr. Samuel Jackson was a learned and accomplished medical man and teacher. In every department, whether at the bedside, or as President of the Board of Health, or in the lecture room, he showed himself the great physician. He filled a chair with eminent success in the University of Pennsylvania from 1825 till 1863 when he resigned. His membership in learned societies as well as his able writings testify to his distinguished ability. (b. March 22, 1787; d. April 4, 1872.)

Dr. Wm. Potts Dewees deserves prominent notice as a physician and author. He possessed a methodical and discerning mind, and was an extensive and careful reader of the best works in the profession. His great powers were brought out at the bedside. He was a good writer, and an admirable oral teacher. His lessons were law in the practice of obstetrics and diseases of women and children. Some of his works ran through many editions. (b. May 5, 1768; d. May 20, 1841.)

Dr. Samuel G. Morton was a conspicuous physician and naturalist. He was a most careful and laborious student, and did a prodigious amount of valuable original scientific work. His love for science, however, did not lessen his devotion to his profession, as his writings on consumption, and other medical works, prove. His fame is enduring, and rests chiefly on his original observations in medicine and craniology. (b. Jan. 26, 1799; d. May 15, 1851.)

Dr. Elisha Bartlett was a highly accomplished scholar and physician. He was a very popular medical teacher, and a ready lecturer, holding chairs in several leading medical colleges. His work on the "Fevers of the United States," published in 1842, at once secured him a place in the front rank of physicians. His purity of life and eminence as a clinical physician, as well as the high character of all his writings, have secured for his name an abiding place in the history of his profession. (b. Oct 6, 1804; d. July 19, 1855.)

Dr. John K. Mitchell was an able physician and a polished writer. He possessed a vigorous intellect, which was well trained and by careful study stored with facts. In the sick room he is said to have had a most encouraging influence over patients and their friends. He was an original thinker, with a vivid imagination, and one of the most charming of lecturers. His writings cover a variety of subjects, all exhibiting ability and versatility of talent. (b. May 12, 1796; d. April 4, 1858.)

Dr. Réné La Roche was a learned physician and author. He was a most laborious and conscientious student, exhausting all sources of information to the fullest extent on whatever subject he took up. He was for

many years connected with the Board of Health of Philadelphia, and was a most valuable member. His practice for years was large and responsible. His studies and writings on yellow fever are a marvel of labor and systematic presentation of all the known facts relating to this disease. (b. 1795; d. December 9, 1872.)

Dr. David Hosack was a celebrated physician, botanist, and author. He had a large practice, and yet found time to lecture in different colleges, and to write exhaustive treatises on medical subjects. He held important positions in the Almshouse, in the New York Hospital, and in the Bloomingdale Asylum. His contributions to medical science are numerous and valuable. (b. August 31, 1769; d. December 22, 1835.)

Dr. John Morgan was a man of learning and an eminent physician and surgeon. He enjoyed the distinction of being the founder of the first medical school in America. At that time he was perhaps the most thoroughly educated and accomplished physician in this country. He was a good writer, and was the first to suggest that pus was formed by a secretory process. He was surgeon-general of the Continental Army, and one of the founders of the American Philosophical Society. (b. 1735: d. Oct. 15, 1789.)

Dr. Josiah C. Nott was a prominent physician and surgeon, and a learned ethnologist. He was a man of commanding powers of intellect, with great industry and capacity for study. While he won a world-wide fame as an ethnologist, he did not neglect the duties of a large practice. He was eminent as a teacher, and as the founder of the Medical College of Mobile. His ethnological writings, however, are those which are best known, but he was equally distinguished as a physician and surgeon. (b. March 31, 1804; d. March 31, 1873.)

Want of time will prevent comment upon all our medical worthies. I however present the following list of names, incomplete though it be, in which it would be difficult to assign a precedence, for all of them have won national reputations, and are eminently deserving of commemoration. I am persuaded that I might more than double the list, and yet not include all who have won reputations that have extended beyond the confines of their own country:—J. Mason Warren, Caspar Wistar, Wm. Shippen, Samuel Bard, Wright Post, Chas. Caldwell, Benjamin S. Barton, Benjamin Waterhouse, David Ramsay, John D. Godman, Wm. E. Horner, Franklin Bache, Robley Dunglison, Warren Stone, John Ware, James Thacher, Wm. W. Gerhard, C. D. Meigs, Hugh L. Hodge, Edward Miller, Wm. Gibson, J. W. Beck, Usher Parsons, Caleb Fiske, J. E. Holbrook, William

Baynham, F. T. Stribling, L. M. Lawson, J. R. Coxe, T. C. James, R. W. Gibbes, John P. Mettauer.

In looking over the available records of the lives of the medical men who have labored in the several States during the century, I am struck with the evidence of the high average professional ability, and wonderful fidelity, with which they have discharged their duties. The testimony, too, is ample as to the high esteem in which the vast majority of medical men have been held by the communities in which they resided.

I am aware there are those who would draw this picture less rosy. And I will concede that the opinion held on the point depends to some extent upon the temperament and motive of the inquirer. If he seeks to find the illiterate, the incompetent, or the unworthy, bearing the title of doctor, I am sorry to say such can be found. But if, on the contrary, he looks as I have done to find the educated, the intelligent, the skilful, the conscientious and faithful physicians, they are to be found in great numbers in every city and village in our broad and prosperous republic. I am persuaded that the medical profession of the United States, notwithstanding all that has been said by its friends in their desire to elevate it, really has within its ranks proportionately more talent, nobility of character, and high scientific acquirements, than are to be found in any other profession in this or any land.

The number of great physicians who have by their discoveries and writings added new facts and extended the boundaries of medical science, is limited in any century and every country. This fact ought not to be lost sight of.

To the young and to the inconsiderate only do great reputations seem a matter of course. To the conceited nothing seems beyond their untried powers. Age and experience, however, demonstrate the limitations and possibilities of human intelligence and acquirements, which, it is conceded by the wisest, are comparatively narrow and circumscribed.

Medical science and the medical profession in America have made vast progress in the hundred years just passed, and have brought into prominence during that time many medical men of genius and rare abilities, and sometimes from unexpected quarters. If there is any one thing in which the American people has a united faith, it is in progress. As a nation and a people we believe we shall be better physically, morally, and intellectually, in the future than we have been in the past.

From a careful study of the average proportion of physicians to population, it is rendered probable that about 65,000 physicians have died in the United States during the century. Of even the few whose genius, skill, and devotion to medicine, in the several States, have rendered their lives notable, it is not possible to present more than the merest outline; little, indeed, beyond an imperfect list of names. To do even this meagre justice to my subject, I was obliged to correspond with physicians in different parts of our country, and beg them to assist me in collecting the necessary facts; and to these gentlemen I wish to return my most sincere acknowledgments for their valuable assistance. Whatever defects appear in this paper, and doubtless there are many, they are my own.

Alabama.[1]—In this State Josiah Clark Nott, a native of South Caro-

[1] Alabama was visited by De Soto as early as 1541. The first successful settlement was made upon Mobile Bay in 1702, by Bienville. This State formed a part of Georgia until

lina, was for years the leading medical spirit. His eminence as a surgeon, author, and teacher, placed him in the front rank; he has already been mentioned. (b. March 31, 1804; d. March 31, 1873.) Dr. J. W. Heustis wrote on the diseases of the South as early as 1817. In 1825 he published a more systematic treatise on the "Bilious and Remittent Fevers of Alabama." (b. 1784; d. 1841.) Dr. Wm. M. Boling, of Montgomery, was a physician of education, and extensively patronized. Dr. Thomas Fearn and his brother Dr. Richard Lee Fearn, of Mobile, were natives of Virginia, and accomplished physicians. Dr. Silas Ames, of Mobile, was a physician of skill, and esteemed remarkably successful in the treatment of fevers. The following also deserve mention, viz.: Drs. Samuel D. Holt, Leroy Anderson, A. Lopez, A. G. Mabry, H. S. Levert, James C. Harris, Nicholas Merriwether, P. H. Lewis, Edward Gant, and R. C. Armstrong.

Arkansas.[1]—Dr. Benj. P. Jett, of Washington, Hempstead Co., came from Virginia, and enjoyed a large and responsible practice. (b. Oct. 25, 1808; d. Dec. 29, 1865.) Dr. Craven Peyton, of Little Rock, served as a surgeon in the war with Mexico, and thereafter retained a preference for the practice of surgery, in which he was very successful. The great esteem in which he was held was manifested by the closure of the banks and business houses, in order that their employés might attend his funeral. (d. Nov. 7, 1872.) Dr. Charles B. Mitchell, a native of Tennessee, practised in Washington. His business habits, intelligence, and enterprise, made him many friends, and caused him to be elected U. S. Senator, 1860–61. (b. Sept. 19, 1815; d. Sept. 20, 1864.) Dr. Shephard Laurie, a native of the District of Columbia, was for many years one of the leading physicians and surgeons of Little Rock. I will also mention Drs. Geo. Eving, Bumford, G. G. Shumard, Alden Sprague, Burton, and Gibson.

California.[2]—This new State holds out such golden promises as to

1802; from this time till 1817 it was included in the Mississippi territory, and was then organized into a separate territorial government, and admitted as an independent State to the Union in 1819. Alabama has advanced rapidly in population and wealth, and has given much encouragement to general education and the advancement of the sciences. In 1870 she had 996,992 inhabitants. She has no large cities; about one in twelve of her people live in cities and towns of over five thousand inhabitants. One medical college exists, located at Mobile. (Note.—Summer schools, as adjuncts to colleges, are in no instance enumerated.) A State Medical Association, formed in 1847, has, by recent legislation, also the legal powers of a State board of health, and publishes a volume of Transactions annually. Institutions, sufficient for the care and treatment of unfortunates, have been established.

[1] In Arkansas settlements were first made about 1685; it was a part of the Louisiana purchase of 1803. In 1819 it was formed into a territory, and was admitted as an independent State in 1836. The population in 1870 was 484,471. It has no large cities, and only about one in thirty of its people live in cities and towns of over five thousand inhabitants. The State in 1870 had 1206 physicians. Its population is gradually increasing. A State Medical Association, formed in 1870, publishes annually a volume of Transactions. Institutions for the care of the insane and other unfortunates have been founded.

[2] The earliest settlement in the territory of the present State of California was in 1769, by a party of Franciscan friars who came from the Peninsula of Lower California In 1821 it became a territory of Royal Mexico, and continued a province under the republic. In 1846 the American navy seized Monterey, and from that time it has been under the control of the United States. The gold mines were discovered in 1848, population was at once led to them, and California was admitted as a State in 1850. She has been, therefore, but a little over a quarter of a century a member of the Union. Her population in 1870 was 582,031. Nearly one-third of her people live in cities of over five thousand inhabitants. She had at the date mentioned 1257 physicians. Two medical colleges have been established, and a State Medical Society, formed in 1870, publishes annually a

attract to it many able physicians. Dr. Thomas M. Logan, a native of South Carolina, in 1849 located at Sacramento. He was a close observer of the causes of disease, and a frequent contributor to the medical journals. He was influential in organizing the Medical Society of California and the State Board of Health, and was president of the latter at the time of his death. He was President of the State Medical Society in 1871, and of the American Medical Association in 1873. (b. Jan. 31, 1808; d. Feb. 13, 1876.) Dr. E. S. Cooper, a native of Ohio, was an excellent surgeon and a successful medical teacher in San Francisco. He founded and published the San Francisco Medical Press, and made valuable suggestions as to the physiological mode of repair in wounded joints and tendons. He was a careful student, a bold surgeon, and a frequent contributor to medical serial literature. (d. Oct. 13, 1862, æt. 40.) Dr. Isaac Rowell, a native of New Hampshire, enjoyed an extensive practice in San Francisco, and was particularly influential in organizing the University of the Pacific, in which he was a professor. (b. 1818; d. Jan. 4, 1871.) Dr. Wm. Burnett, of Petaluma, was a physician of culture. The following also deserve mention: Drs. Henry M. Gray and John T. Morse, of San Francisco.

Connecticut.[1]—Dr. Aneas Munson, of New Haven, served as a surgeon in the Revolutionary war. He was an observing and successful practitioner and surgeon. He contributed papers to the Connecticut Medical Society, and was an active promoter of art and science. He was one of the originators of the State Medical Society, and for some years its president. (b. June 24, 1734; d. June 16, 1826.) Dr. Jared Potter, of Wallingford, was a scholar, and had a passion for acquiring knowledge. His office was much frequented, and his instruction eagerly sought by young men entering the profession. (d. 1810, æt. 67.) Dr. Jonathan Knight, of New Haven, was remarkable for his urbanity and sound professional judgment. He held a chair in Yale College for twenty-five years. He was the first president of the American Medical Association. (b. Sept. 4, 1789; d. Aug. 25, 1864.) Dr. Wm. Tully was an earnest cultivator of the science of medicine. He was an author of merit, and published, along with Dr. Thomas Miner, in 1823, a work on fevers. (d. Feb. 28, 1859.) Dr. Thomas Miner was one of the founders

volume of Transactions. A State board of health, which also publishes annual Transactions, has been established by law. Institutions for the care of unfortunates have been created by the State, sufficient for the wants of the people.

The following medical journals have been published: California Medical Gazette, 1868; California State Medical Journal, 1856; Medical Gazette, 1870; Pacific Medical and Surgical Journal, 1858; San Francisco Medical Journal, 1858; San Francisco Medical Press, 1860; Western Lancet, 1872.

[1] Connecticut is one of the thirteen original States. The Dutch had a trading house at Hartford as early as 1631. An offshoot of Plymouth had also a settlement at Windsor about the same time. New Haven was for some years an independent colony. All the separate interests, however, were consolidated in 1665. The State took an early and an active stand in favor of American Independence. The population in 1870 was 537,454, with about two-thirds of the people living in cities and towns of over five thousand inhabitants. At the same time there were 680 physicians. Great encouragement has been given to education and the advancement of science. A State Medical Society was founded in 1792, and was one of the first in the country to publish Transactions. There is one medical college, a department of Yale. It was in this State that anæsthesia in surgical operations was first tried. The first school in America for the education of the deaf and dumb was organized at Hartford. Institutions for the care of the insane and other unfortunates have been founded by the State, sufficient for the wants of the people.

The following journal of a medical and scientific character has been published in Connecticut: American Journal of Sciences and Arts, 1846.

of the Medical Department of Yale College. He was particularly interested in the cure and treatment of the insane. His life and labors were important to his day and generation. (d. April 23, 1841.) Dr. Eli Todd, of Hartford, was an educated and intelligent physician. He was much interested in the treatment of the insane, and was chosen superintendent of the Retreat at Hartford. (d. Nov. 17, 1833.) Dr. Lemuel Hopkins, of Hartford, was a scholarly physician, writer, and wit. He was devoted to scientific studies and to the elevation of the profession. (b. June 19, 1750; d. April 14, 1801.) Dr. Eli Ives, of New Haven, was a distinguished physician and botanist. He was a man of quick perceptions, sound judgment, great industry and perseverance. For years he filled with ability a professorship in Yale College, and in 1860 was President of the American Medical Association. (b. Feb. 7, 1779; d. Oct. 8, 1861.) Dr. Mason F. Cogswell was a surgeon of the Revolution, and during his day the leading surgeon in Connecticut; he was the first person in this country to ligate the carotid artery. (b. 1761; d. Dec. 1836.) Dr. Thomas Hubbard succeeded to the chair of surgery in Yale College on the death of Dr. Nathan Smith, and was a worthy successor to one of America's most eminent surgeons. (d. June 18, 1838, æt. 63.) Dr. Worthington Hooker, of New Haven, was an accomplished physician and a writer of many educational works of merit. His brother Charles also enjoyed an enviable reputation. (b. March 3, 1806; d. Nov. 6, 1867.) I will also name Drs. Seth Bird, George Sumner, Samuel Woodward, Daniel Worden, and Horace Wells, the dentist and discoverer of anæsthesia.

DELAWARE.[1]—Dr. Edward Miller was an accomplished writer. He practised at Dover until 1796, when he removed to the city of New York. His reputation had preceded him, so that he rapidly acquired a lucrative business. In connection with Drs. E. H. Smith and S. L. Mitchell, he founded in 1797 the New York Medical Repository, the first medical journal in our country. (b. May 9, 1760; d. March 17, 1812.) Dr. James Tilton, of Wilmington, served as a surgeon in the hospitals of the Revolution, and proved himself remarkably well informed on the subject of hospital construction and management. He was a member of the Continental Congress from 1783 to 1785. During the war of 1812 he was appointed Surgeon-General of the U. S. Army. In 1813 he published a pamphlet on Military Hospitals. He was a man of clear perceptions and practical good sense, and in his official position did much to promote the efficiency of the medical department of the army. He was President of the Delaware State Medical Society. (b. June 1, 1745; d. May 14, 1822.) Dr. James Sykes was a physician of great personal and professional popularity; and was chosen to represent his district in

[1] Delaware was one of the thirteen original States. It has the smallest area of any State except Rhode Island. The earliest settlements were made by the Swedes and Finns in 1627. The Dutch of New York held the government in the year 1655, but it passed to the English in 1764. Delaware formed a part of the Pennsylvania grant of 1682, under the name of the "Three Lower Counties of Delaware." In 1701 it was permitted, in part, to have a separate government, but was subject to the Governor of Pennsylvania down to the Revolution. Delaware's population in 1870 was 125,015, about one in four of her people living in cities of over five thousand inhabitants. She had at the same time one hundred and seventy physicians. Her proximity to Philadelphia, and her position on the Delaware Bay, give her great commercial and manufacturing advantages. Her population and wealth are steadily increasing. She has a State Medical Society, formed in 1789, which publishes Transactions annually, and she has made ample provisions for the care and treatment of her insane and other unfortunates.

the State Legislature, and also in the State Senate for fifteen consecutive years, being much of the time the presiding officer. In 1801–2 he was acting Governor. He practised for a few years in the city of New York, but returned to Delaware, where he ended his days. (b. March 27, 1761; d. October 18, 1822.) Dr. James Couper, of New Castle, was a highly gifted physician. In 1840 he was a delegate from the State Medical Society to the Convention for revising the U. S. Pharmacopœia. He was President of the Delaware State Medical Society, and Vice-President of the American Medical Association in 1863. (b. Oct. 3, 1803; d. 1865.) Dr. Henry F. Askew was a physician of sound judgment and great experience. His professional life was characterized by close attention to professional duties. He had a well-trained mind, was a constant reader of the latest literature, and had a high regard for the dignity of the profession. He was President of the American Medical Association in 1867. (d. March 6, 1876.) Dr. George Munroe was a surgeon in the Revolutionary War. He practised at Wilmington, and was through life one of the foremost medical men of the State, and an occasional contributor to the "New York Medical Repository." (d. Oct. 11, 1819.) Dr. John Vaughn, a native of Pennsylvania, was a man of science and physician of ability. His manners in the sick room were gentle and assuring. In the winter of 1778–79 he delivered a course of lectures on Chemistry and Natural Philosophy. In the following year he published a "Chemical Syllabus;" he also contributed articles to the "New York Medical Repository." (d. March 25, 1807.) I will also name the following: Drs. Charles Ridegley, Allin McLane, Wm. Gibbons, Henry Latimer, Nicholas Way, John McKinley, Ebenezer Smith, Joseph Hall.

District of Columbia.[1]—Dr. Thomas Sewall, a native of Maine, was for many years extensively engaged in practice in Washington. He held the chair of Anatomy in the Medical Department of Columbia College from its organization in 1825 until 1839, and from that time to his death the chair of Pathology and Theory and Practice. His address at the opening of the school in 1825 gave a history of the Medical Colleges of the country up to that time. He was a good writer, and published a number of papers on Phrenology, Temperance, and Medicine. (d. April 10, 1845.) Dr. Tobias Watkins, a native of Maryland, was a physician, scholar, and author. He published in Baltimore, in 1809, "The Medical and Philosophical Recorder," and was for a time one of the editors of the "Portfolio." He served as a surgeon in the war of 1812, and was acting Surgeon-General from 1818 to 1821, and Fourth Auditor of the Treasury from 1824 to 1829. He translated a number of medical works from the French. (d. Nov. 14, 1855.) Dr. Thomas Henderson was a physician and surgeon of the U. S. Army, and an author. From 1825 to 1833 he was Professor of Theory and Practice in the Medical Depart-

[1] For three-quarters of a century Washington has been the seat of the government of the United States. Originally, the District or Territory of Columbia comprised a territory of ten miles square, but that part of it lying south of the Potomac River, containing thirty-six square miles, was retroceded to Virginia in 1844. The population in 1870 was 131,700. At the same time there were three hundred and twenty-six physicians. There are three medical colleges now giving instruction. A district medical society was organized in 1817, and publishes Transactions. Institutions for the care of insane and other unfortunates, sufficient for the wants of the District, have been established by the United States government.

The following Medical Journals have been published in the District of Columbia: American Botanical Register; National Med. Journal, 1870; Register and Library of Medical and Chirurgical Science, 1835.

ment of Columbia College. After his admission to the army he published "Hints on Examination of Recruits for the Army," which has gone through several editions. (b. Jan. 6, 1789; d. Aug. 11, 1854.) Dr. B. S. Bohrer, of Georgetown, was a fine scholar and an accomplished physician. He held for some years a chair in the Ohio Medical College. He possessed a fine library of medical and classical literature. He was a good practitioner, and a man of most courteous and agreeable manners. (d. Aug. 19, 1862.) Dr. Joseph Lovell, a native of Massachusetts, was Surgeon-General of the Army, and long a resident of Washington. Although not engaged in private practice, he was a member and supporter of the local medical organization, and was frequently called in consultation. (b. 1788; d. Oct. 17, 1836.) Dr. Thomas Lawson, a native of Virginia, was a surgeon in the army, and held the office of Surgeon-General. He was a man of great professional abilities and personal worth, and made a number of valuable reports on the diseases of the army and the climate of the western military posts. (d. May 15, 1861.) Dr. Frederick Dawes was a physician of fine abilities, and enjoyed for years an extensive practice. (d. Feb. 10, 1852.) To these I will add the names of Drs. Frederick May, Bailey Washington, R. K. Stone, Thomas Miller, John M. Thomas, the two Worthingtons, R. H. Coolidge, J. A. Brereton, and Joshua Riley.

Florida.[1]—Dr. Bosquet was a physician of note at St. Augustine, as early as 1800. Dr. Thomas Travers was in practice there in 1812. About the time the territory was purchased from Spain, Dr. Darcy was a leading physician. Dr. Henry Perrine was a physician, and a man of scientific attainments. The United States gave him a township of land near Biscayne Bay, for the purpose of encouraging the introduction and cultivation of tropical plants. The "Sisal Hemp" is now growing abundantly in Florida, the result of his enterprise. The Doctor was murdered at the light-house, by the Indians, during the Florida war (1841). Dr. Lewis practised as early as 1813, at Fernandina, and enjoys the distinction of having introduced vaccination into that section of country. Dr. Charles W. McCroskey was a good physician. He was connected with the army at St. Augustine, and died of yellow fever. Dr. W. H. Simmons, a native of South Carolina, lived at St. Augustine. He was a physician of skill, and a man of literary accomplishments. Dr. Richard Weightman, a native of Washington city, after serving in the army, settled on the St. John's River, and engaged for years in the practice of his profession. Dr. Seth Peck was also a physician of note in Florida. To the names already mentioned, I will add those of Drs. Lewis Willis, W. W. Waddell, Andrew Anderson, Theodore Turnbull, and William Davis.

Georgia.[2]—Dr. Lyman Hall was a well-educated physician, a member

[1] Florida was visited by Ponce De Leon in 1512, and in 1536 by De Soto. A settlement was made in 1564, the earliest by Europeans in any State of the Union. Florida belonged to Spain till 1820, when it was purchased by the United States, and admitted as an independent State in the Union in 1845. It has a large territory with almost tropical climate, but a sparse population. In 1870 it had 188,248 inhabitants. The census gave it 240 physicians. There are no large cities in the State. The United States Government maintains a navy yard, and also a military garrison. The State has a Medical Association, formed in 1874, which publishes annual Transactions. Provision has been made for the care and treatment of the insane, and other unfortunates.

[2] Georgia is one of the thirteen original States. The first settlement by the English was in 1732, the latest of any of the American Colonies. The population at the close of the Revolution did not reach 30,000. The population in 1870 was 1,184,109, with about one in every fourteen living in cities and towns of over five thousand inhabitants. It had at the

of the Continental Congress, and a signer of the Declaration of Independence. (b. 1725; d. Oct. 19, 1790.) Dr. Milton Antony, of Augusta, was a teacher and practitioner of ability. He was the founder of the Medical Academy at Augusta, in 1828, and of the Medical College of Georgia. In 1831 he started the first medical journal published in the Southern States. (b. August 7, 1789; d. Sept. 19, 1839.) Dr. Noble Wimberly Jones was a physician and a patriot. In the discharge of his professional duties he was attentive and skilful. Dr. W. C. Daniell, of Savannah, was a physician and author of note. His best known work is entitled, "Observations on the Autumnal Fevers of Savannah." In 1826 he advocated the use of capsicum internally and externally in yellow fever. (b. January, 1792; d. Dec. 28, 1868.) Dr. Richard Banks, of Savannah, and a native of Georgia, was a physician and surgeon of ability, and filled the chair of Surgery in the Savannah Medical College. (d. May, 1856, aged 62.) Dr. R. D. Arnold, of Savannah, a native of Georgia, was an accomplished physician and writer. He was one of the original members of the American Medical Association, and its Vice President in 1852. He was for many years Professor in the Savannah Medical College. He wrote and published papers of decided merit in the Transactions of the American Medical Association, and in the Medical Journals. (d. July 10, 1876, æt. 68.) Dr. W. R. Waring was for many years a leading physician of Savannah, and Professor in the Medical College. Dr. George M. Newton was a physician and successful teacher of Anatomy at Augusta. He left a fortune of about $200,000, to found an orphan asylum. (b. Jan. 30, 1810; d. Jan. 6, 1859.) In addition to the foregoing, I will name Drs. Tomlinson Fort, of Milledgeville, Thomas N. Hamilton, of Rome, G. B. Gorman, Charles W. West, Joseph H. Eve, of Augusta, Dr. Wildman, of Savannah, and Dr. Curtis B. Notingham.

Illinois.[1]—Dr. Daniel Brainard, a native of New York, was a physician and surgeon of distinction. He settled in Chicago as early as 1835, and soon acquired a leading professional business, especially in Surgery. He was one of the founders of the Rush Medical College, and long one of its

same time 1537 physicians. It has one good seaport, but no large cities. It has three medical colleges, distributed, one each, at Atlanta, Augusta, and Savannah; a State Medical Association was formed in 1849, and a State Board of Health has been organized and publishes reports. Institutions for the care of the insane and other unfortunates have been established.

The following medical journals have been published in Georgia: Atlanta Medical and Surgical Journal, 1855; Georgia Medical Companion, 1871; Georgia Medical and Surgical Encyclopædia, 1860; Oglethorpe Medical and Surgical Journal, 1861; Savannah Journal of Medicine, 1858; Southern Medical and Surgical Journal, 1837.

[1] The French had trading posts in Illinois as early as 1700. The earliest permanent settlement, however, was by the French about 1763. In 1783 this State formed a part of the "Northwestern Territory." In 1800 it was a part of the territory under the name of Indiana. Illinois was admitted as an independent State in the Union in 1818. Her population in 1870 was 2,539,891, with about one in five of her people living in cities and towns of over five thousand inhabitants. She then had 4861 physicians. Population and wealth are rapidly accumulating in this State. Three medical colleges are now giving instruction. A State Medical Society was organized in 1851, and publishes a volume of Transactions annually. Institutions for the care of unfortunates have been established, sufficient for the wants of the people.

The following medical journals have been published in Illinois: American Journal of Materia Medica, 1860; Chicago Journal of Nervous and Mental Diseases, 1874; Chicago Medical Examiner, 1860; Chicago Medical Journal, 1858; Chicago Times, 1869; Illinois and Indiana Medical and Surgical Journal, 1846; Illinois Medical and Surgical Journal, 1844; Lens, 1872; Northwestern Medical and Surgical Journal, 1849; Pharmacist, 1868; Tripod, 1871.

professors. He contributed articles of value to the Medical Journals, and to the Illinois State Medical Society's Transactions. (b. 1812; d. Oct. 10, 1866.) Dr. Wm. B. Herrick, a native of Maine, was one of the early physicians of Chicago. He served as a surgeon in the Mexican war, and was a physician of extensive experience and skill. He filled the chair of Anatomy in Rush Medical College with ability for twenty years. (d. Dec. 31, 1865.) Dr. Henry Wing settled in practice in Collinsville. He was a physician of education, and a scientist of extensive acquirements. He was one of the founders of the Chicago Medical College, and for years, held in it a professorship. His notes on the Botany of the Rocky Mountains form a part of Prof. Powell's Geological Report of that region. (b. 1822; d. Feb. 18, 1871.) Dr. Elijah D. Harmon, a native of Vermont, was one of the earliest physicians to settle in Chicago. He was physician to the Military Post of Fort Dearborn in 1832. He was a good physician and surgeon, and for his day, and the demands made upon his skill, was an efficient and successful practitioner. (b. Aug. 20, 1782; d. July 3, 1869.) Dr. J. V. Z. Blaney, a native of Delaware, was an educated and successful physician. He was one of the founders of the Rush Medical College, and the originator and publisher, in 1844, of the "Illinois Medical and Surgical Journal." (b. 1820; d. Dec. 11, 1874.) Dr. Rudolphus Rouse, a surgeon of the war of 1812, settled in practice in Peoria. He deserved, and soon attained, the first rank among physicians in that part of the State. (b. July 20, 1793; d. April 30, 1873.) The following physicians are also deserving of mention: Drs. Samuel Thompson, George W. Richards, Nicholas Hard, Harrison Noble, Stephen W. Noble, Levi T. Hewins, Josiah Goodhue, Alexander Walcott.

INDIANA.[1]—Dr. John Thomas Plummer, a native of Maryland, was a learned physician and excellent practitioner. He enjoyed in Indianapolis and its vicinity, a high reputation for skill and devotion to professional duty. In the natural sciences he was quite proficient, and was an excellent philologist; he assisted Noah Webster in collecting and defining the meaning of Western words for his unabridged Dictionary. (d. April 10, 1865, aged 58.) Dr. Isaac Casselberry, a native of Indiana, and long a leading physician in Evansville, added to skill in his profession a love of study, and good business habits. He was a successful promoter of medical organizations, and in every new enterprise worked with great intelligence and success. He was a member of the Board of Health, and a trustee of the Evansville Medical College, also President of the State Medical Society. (b. Nov. 26, 1821; d. July 9, 1873.) Dr. Charles Parry, of Indianapolis, was especially careful in diagnosis, and was a superior surgeon. He possessed the ability to make original observations, and was a writer of force. Prof. Geo. B. Wood quotes from a paper of his on pernicious fever. (d. August, 1861.) Dr. Asahel Clapp, a native of Massachusetts, practised with great success in New Albany, where he settled in 1817,

[1] Indiana was admitted to the Union in 1816. There were in it a few French settlements as early as about 1700. Immigration from the old States commenced about 1802. The population in 1870 was 1,680,637. It has no very large cities, about one in eight of its population living in cities and towns of over five thousand inhabitants. It had at the same time 3615 physicians. It has a State Medical Society, formed in 1849, which publishes annually a volume of Transactions, and has three medical colleges giving instruction. Institutions sufficient for the care of unfortunates have been established.

The following medical journals have been published in Indiana: Indiana Journal of Medicine, 1870; Indiana Journal of Medicine and Surgery, 1855; Indiana Medical Journal, 1854; Indiana Scalpel, 1860; Western Retrospect of Medicine and Surgery, 1872.

and was for forty years actively engaged in the duties of his profession. He was a good botanist, and made a report to the American Medical Association on the medicinal plants of the United States. He was fond of the study of the natural sciences, and collected a large cabinet of specimens which he presented to Yale College. Dr. John L. Richmond, a native of Massachusetts, although a well-read and intelligent physician, won his reputation by a single operation. He performed the Cæsarean section on the 23d of April, 1827, in a log cabin in the country, with no assistance except that rendered by the husband of the patient, and two women. The operation was successful, saving the mother's life. The child died. (b. April 5, 1785; d. Oct. 12, 1855.) Dr. John S. Bobbs, a native of Pennsylvania, was a successful physician and teacher of medicine in Indianapolis. He was for some years Professor of Surgery in the Indiana Central Medical College. In his will he left means for the establishment of a public Dispensary. He was President of the State Medical Society in 1868. (b. Dec. 28, 1809; d. 1870.) In addition to the above list, I will name Drs. T. Fry, E. Demming, V. Kersey, and J. W. Moody.

IOWA.[1]—Dr. David L. McGugin, a native of Pennsylvania, served as a surgeon in the Mexican war, and was for years the leading physician of Keokuk. He filled a chair in the University of Iowa at the time of his death. The State Medical Society in 1851 elected him President. As a practitioner he had no superior in the State. (b. 1807; d. June 23, 1865.) Dr. George Reeder, a native of Maryland, and a graduate of William and Mary College, Va., was a successful practitioner of medicine at Muscatine. He was one of the founders of the State Medical Society, and its President in 1854. The following also deserve mention: Drs. Ezra T. Fountain and G. W. Richards.

KENTUCKY.[2]—Dr. Benjamin W. Dudley, a native of Virginia, was an eminent surgeon and teacher at Lexington. After graduating, he spent four years in Europe perfecting himself in his professional studies. In 1817 he was elected Professor of Anatomy and Surgery in Transyl-

[1] Iowa was admitted into the Union in 1846. It was a part of the Louisiana purchase of 1803. Its earliest settlements were by the French. In 1870 it had a population of 1,194,320, with about one in ten of the population living in cities and towns of over five thousand inhabitants. It had at that time 1865 physicians. It has a rich and productive soil, and is rapidly increasing in wealth and population. Two medical colleges are giving instruction. A State Medical Society was founded in 1850, and publishes an annual volume of Transactions. Institutions sufficient for the care of the insane and other unfortunates have been established.

The following medical journal has been published in Iowa: Iowa Medical Journal, 1855.

[2] Kentucky was admitted to the Union in 1792. The first account we have of this region was by Dr. Thomas Walker, of Virginia, who visited it in 1745, and again in 1750. Dr. John Connolly had made location of a tract of land at the falls of the Ohio as early as 1770. The earliest emigrations to Kentucky were under Daniel Boone, who made a settlement at Harrodsburgh in 1774. The soil is very rich and productive; wealth and population are rapidly flowing in. The population in 1870 was 1,321,011, with about one in seven of her people living in cities and towns of over five thousand inhabitants. She had then 2414 physicians. Four medical colleges are now giving instruction in the State, and a State Medical Society, formed in 1851, publishes Transactions annually. Institutions for the care of unfortunates, demanded by enlightened humanity, have been established.

The following medical journals have been published: American Medical News, 1876; American Medical Weekly, 1874; American Practitioner, 1869; Kentucky Medical Recorder, 1853; Louisville Journal of Medicine and Surgery, 1838; Louisville Medical Journal, 1860; Louisville Medical Gazette, 1859; Louisville Review, 1856; Richmond and Louisville Medical Journal, 1868; Transylvania Medical Journal, 1849; Transylvania Journal of Medicine and Science, 1828; Western Journal of Medicine and Surgery, 1840 Western Lancet, 1842; Western and Southern Medical Recorder, 1841.

vania University. Through life he devoted himself strictly to the duties of his profession. He remained connected with Transylvania University till 1850, when he retired from practice, and lived in quiet on his farm. He was a bold surgeon and successful operator. He performed lithotomy 225 times, and did not lose a patient until after he had operated more than 100 times. He had a genius for originating new operations and devices. He contributed many articles of great value to medical journals, chiefly on surgery, but wrote no large work. (b. 1785; d. Jan. 20, 1870.) Dr. Charles W. Short, of Lexington, was a learned botanist, and an accomplished physician and teacher. He held the chair of Botany and Materia Medica in the Transylvania University. He published but little. His best known writings are his contributions to the Flora of Kentucky. Dr. Ephraim McDowell, a native of Virginia, originated the surgical operation of ovariotomy, which at first was severely condemned, but which is fully justified by the success attending the proceeding. (b. November 11, 1771; d. July 25, 1830.) Dr. Henry Miller, a native of Kentucky, was an obstetrician, writer, and teacher of ability. In 1835 he was appointed to the chair of Obstetrics in the Medical Institute at Louisville. He was the first physician in the West to use the speculum, and to practise local applications in diseases of the uterus. He was in many respects one of the most original and skilful physicians that Kentucky has produced. (b. Nov. 1, 1800; d. Feb. 8, 1874.) Dr. Samuel Brown, a native of Virginia, introduced vaccination in Lexington, as early as 1802. He was a man of decided ability, but exhibited a restless disposition, removing to New Orleans, then to Natchez, Miss., then to Huntsville, Ala., and finally returning to Lexington. He held the chair of Theory and Practice in Transylvania University. He was very entertaining as a lecturer. Contributions from his pen were published by the American Philosophical Society, and in the New York Medical Repository and other medical journals. As early as 1820 he suggested the formation of an American Medical Association. (b. Jan. 30, 1769; d. July 12, 1830.)

Dr. James Bush, of Lexington, filled with ability the chair of Surgery in Transylvania University from 1839 to the time of his death. (b. 1808; d. Feb. 9, 1875.) Dr. Wm. H. Richardson was a physician of high culture, and Professor of Obstetrics in the Transylvania University. He was a man of superior education and address, and enjoyed a large practice. Dr. Joshua Barker Flint, a native of Massachusetts, practised for some years in Boston, but removed to Louisville, where he held the chair of Surgery in the Louisville Medical College from 1837 to 1849, and, from this time to his death, the same chair in the Kentucky School of Medicine. In 1868 he published a work on Practice. He was the first surgeon in Kentucky who administered ether to produce insensibility for surgical operations, which he did in 1847. Dr. Charles Caldwell was an eminent physician, author, and teacher. As early as 1810 he filled the chair of Natural History in the University of Pennsylvania. In 1818 he was elected to the chair of Theory and Practice in the Transylvania University, which he held till 1837. He was a ready and voluminous writer. (b. May 14, 1772; d. July 9, 1853.) Dr. John Esten Cooke was a physician, author, and teacher of ability, and practised with success in the Shenandoah Valley of Virginia, and assisted in establishing the Winchester school, before removing to Kentucky. In 1827 he was elected to the chair of Theory and Practice in the Transylvania University. In connection with Prof. Short he founded the following year "The Transylvania Journal of Medicine." In 1828 he published a work

entitled "Pathology and Therapeutics." Dr. Lewis Rogers fairly won his high reputation by his intelligence and devotion to professional duties. From 1849 he filled a chair in the University of Louisville. He was President of the State Medical Society in 1873, and gave in his opening address an admirable history of medicine in Kentucky. (b. Oct. 12, 1812; d. June 17, 1875.) Dr. J. D. Jackson, of Danville, was, for his age, one of the most accomplished physicians and surgeons of Kentucky. He originated the movement for the erection of a monument to Ephraim McDowell. He performed with success many capital operations, including ovariotomy and tracheotomy. (b. Dec. 12, 1834; d. Feb. 8, 1874.) Beside the physicians named, I will mention Drs. Joseph Buchanan, Daniel L. Metcalf, Ethelbert L. Dudley, Robert Breckenridge, W. A. McDowell, James Fishback, Elisha Warfield, T. L. McLary, Walter Brashiers, Charles McCreary, and Frederick Ridgley.

LOUISIANA.[1]—Dr. Rouanet was a native of France, but in 1844 settled in New Orleans, where he soon acquired a leading position in the profession. He won high encomiums for his studies of the diseases of the heart in Paris, and contributed a number of papers to the French Academy on the physiological and pathological sounds of the heart. In New Orleans he gave office instruction to medical men and advanced students, but was not a teacher in any medical college. His practice for years was large and responsible, and he was recognized by the profession everywhere as a leading authority on diseases of the heart. (d. 1865.) Dr. Warren Stone, a native of Vermont, settled in New Orleans in 1832, and rapidly acquired business and professional reputation. In 1836 he was chosen to lecture on Anatomy in the University of Louisiana, and in 1837 was elected Professor of Anatomy and Surgery, continuing to hold this chair until he resigned in 1872. Throughout the South he was without a rival as a surgeon. In 1870 he was Vice-President of the American Medical Association. (b. 1808; d. Dec. 6, 1872.) Dr. John Hoffman Harrison, a native of Washington, D.C., was surgeon to Charity Hospital from 1833 to 1836. He originated and edited the New Orleans Medical and Surgical Journal. He contributed a number of papers on yellow fever, and wrote a work on the Nervous System. (b. Aug. 30, 1808; d. March 19, 1849.) Dr. Thomas Hunt, a native of South Carolina, settled in New Orleans in 1833. He was one of the founders of the Louisiana Medical College, was popular as a teacher, and a good writer. He was esteemed

[1] Louisiana was admitted to the Union in 1812. Settlements were made at Biloxi as early as 1699, but the earliest successful settlement was at New Orleans in 1712. Louisiana was purchased by the United States from France in 1803. It included all the territory west of the Mississippi, east of Mexico, and south of the British possessions. In 1810 the United States Census gave a population of 76,576. The population in 1870 was 726,915, with about one-fourth of her people living in cities and towns of over five thousand inhabitants. There were at this time 936 physicians. The soil of the State is alluvial and exceedingly rich, but much of it is rendered unfit for cultivation by overflow, checking agricultural production and the increase of population. The situation of New Orleans, at the mouth of the largest river in the world, gives it great commercial importance. A large and well-conducted hospital, known as "Charity Hospital," was rebuilt in 1815. Two medical colleges are now giving instruction. For many years a State Board of Health, having also cognizance of the health of the city of New Orleans, has existed, which reports to the Legislature and publishes a volume of Transactions annually. There is no State medical society, though medical organizations exist in the large cities.

The following medical journals have been published: New Orleans Journal of Medicine, 1868; New Orleans Medical Journal, 1844; New Orleans Medical News and Hospital Gazette, 1854; New Orleans Medical Record, 1866; New Orleans Medical and Surgical Journal, 1844; New Orleans Medical Times, 1861; New Orleans Monthly Medical Register, 1851; Union Medicale de la Louisiane, 1852.

specially successful in the treatment of yellow fever. (b. May 18, 1808; d. March 20, 1867.) Dr. Edward Barton, a native of Virginia, practised with success in New Orleans. He filled the chair of Materia Medica and Therapeutics in the University of Louisiana from 1835 to 1840. His writings on Meteorology, on Hygiene, and on Yellow Fever, show much research and professional experience. In addition I will name Drs. John Leonard Riddell, the inventor of the binocular microscope, J. Jones, Wm. M. Carpenter, Charles A. Luzenburg, and Frank Hawthorn.

MAINE.[1]—Dr. Stephen Cummings, of Portland, was a leading physician in extensive practice as early as 1800, and continued actively engaged in his profession for over 50 years. (b. 1773; d. 1854.) Dr. James C. Bradbury, a native of Maine, settled in practice at Oldtown, and for 35 years enjoyed the confidence of the community. Although not a surgeon, he performed such operations as became necessary in his practice, and on Oct. 11, 1851, amputated at the hip-joint with success. This was the fourth operation of the kind in America. (b. 1806; d. Oct. 3, 1865.) Dr. Amos Nourse, a native of New Hampshire, a physician of Belfast, Maine, and a surgeon of ability, although advanced in years, served in the late war as surgeon of the 20th Maine Regiment. He had been honored by the Presidency of the State Medical Society. Dr. Job Holmes, a native of Maine, settled in Paris, where he enjoyed a large practice. In a few years he removed to Calais, where he passed the remainder of his life in the active duties of his profession. Dr. Hosea Rich, a native of Massachusetts, was a practitioner of note in Bangor. His professional career began as early as 1805, and was continued till 1865. During the war of 1812, he was the surgeon of the 4th Maine Regiment. I will also name Dr. James Parker, who was a physician of ability, and in active practice for over 50 years. He served two terms in Congress.

MARYLAND.[2]—Dr. John Beale Davidge was a fine classical scholar and an extensive reader of the early masters in medicine. As early as 1798, he published an essay on autumnal and intermittent fevers. He was conspicuous and influential in the founding of the Medical Department

[1] Maine was admitted into the Union in 1820. From its settlement, in 1607, it was a part of Massachusetts, and remained under her control till admitted as an independent State. The population in 1870 was 626,915, about one-third of the people living in cities and towns of over five thousand inhabitants. The number of physicians was 818. One medical college, a department of Bowdoin College, is giving instruction. There is a State Medical Society, formed in 1834, that publishes Transactions annually. Institutions for the care of unfortunates have been founded, sufficient for the wants of the people.

The following medical journals have been published in Maine: Journal of the Medical Society of Maine, 1834; Maine Medical and Surgical Reporter, 1858.

[2] Maryland is one of the thirteen original States. Its earliest settlement was in 1634. The population in 1870 was 780,892, one-third of her people living in cities and towns of over five thousand inhabitants. The number of physicians was 1251. The State has great advantages for ocean commerce, owing to its situation on the Chesapeake Bay. It is rapidly increasing in wealth and population. There are three medical colleges giving instruction. Institutions for the relief of the insane and other unfortunates, have been established. There are also a State Medical Society, formed in 1789 under the name of The Medical and Chirurgical Faculty of Maryland, and a State Board of Health.

The following medical journals have been published in Maryland: Baltimore Journal of Medicine, 1861; Baltimore Medical Journal, 1870; Baltimore Medical and Philosophical Lyceum, 1811; Baltimore Medical and Physical Recorder, 1808; Baltimore Medical and Surgical Journal, 1833; Baltimore Monthly Journal of Medicine and Surgery, 1830; Baltimore Philosophical Journal and Review, 1823; Baltimore Physician and Surgeon, 1872; Maryland Medical Recorder, 1829; Medical Bulletin, 1868; North American Archives of Medical and Surgical Science, 1834; Vaccine Inquirer, 1822.

of the University of Maryland. In 1813, he published a new classification and nomenclature of diseases, in Latin. From 1814 to 1816, he published a work in parts, entitled "Physical Sketches," and was a contributor to Medical Journals. (d. 1829, æt. 60.) Dr. Horatio Jameson, of Baltimore, was a native of Maryland, and Professor of Surgery in the University of Maryland. In 1829 he started and edited with ability the Maryland Medical Recorder, which he continued until 1832. One of his best known works is on cholera. He published a pamphlet on the parts concerned in lithotomy. He was fond of the study of the natural sciences, and was a good geologist. In 1830, he attended a meeting of naturalists and physicians, in Hamburg, Germany. Dr. Nathaniel Potter was one of the original founders of, and filled for over thirty years, with distinguished ability, a chair in, the University of Maryland. His writings show much erudition as well as original observation. In 1805, he published a paper on the medical and deleterious properties of arsenic. The best known work from his pen is one on contagion and yellow fever, published in 1817. (b. 1770; d. July 2, 1843.) Dr. Tristram Thomas was a physician of large practice and great influence, on the Eastern Shore of Maryland. He was actively engaged in practice for over 50 years, and was an ardent lover of his profession, studious and observing, and an occasional contributor to the medical journals. His best known paper was one on Bilious and Remittent Fevers, which is referred to favorably in Eberle's Practice. (b. Dec. 25, 1769; d. Aug. 5, 1847.)

Drs. John and Thomas H. Buckler, brothers, were men of fine intellect, and good practitioners. For many years, they held the very front rank as skilful and able physicians. Dr. Philip Thomas, a native of Maryland, practised in Frederick, from 1769 to 1815. He attended the second course of lectures delivered in Philadelphia, under Morgan and Shippen. He was a good scholar, a man of correct habits, and of large influence in the profession of the State. (b. June 11, 1747; d. April 25, 1815.) Dr. John Archer, a native of Maryland, was noted as having introduced the use of senega in croup, and enjoyed the distinction of having been the first person that received a diploma from an American Medical College, which he did in Philadelphia, in 1768. He served in the State Legislature, and as a member of Congress, from 1801 to 1807. I will also mention Drs. Charles Frick, Samuel Baker, Frederick Dorsey, Ennals Martin, Miles Littlejohn, John Tyler, the two Murrays, of Annapolis, Samuel K. Jennings, John Baltzell, Gustavus Brown, Elisha Butts, and R. S. Stewart.

MASSACHUSETTS.[1]—Dr. Edward Augustus Holyoke, a native of Massa-

[1] Massachusetts was one of the thirteen original States, and the first to raise troops and to inaugurate the measures that led to armed resistance to the claims of Great Britain, and to American Independence. Settlements were made in her territory as early as 1620. She soon after began a system of public education, which has been developed and adopted in all the States. Her population in 1870 was 1,457,351, nearly one-half of her people living in cities of over five thousand inhabitants. She had 2047 physicians. One medical college, a department of Harvard University, has existed since 1782. Institutions on the most approved plans, for the care of unfortunates of all classes, have been established on a liberal scale. A State Medical Society, formed in 1781, publishes Transactions, and a systematic registration of vital statistics has been in successful operation for many years.

The following medical journals have been published in Massachusetts: Berkshire Medical Journal, 1861; Boston Journal of Chemistry, 1866; Boston Medical Intelligencer, 1823; Boston Medical and Surgical Journal, 1828; Journal of the Gynæcological Society, 1869; Medical and Agricultural Register, 1806; Medical Magazine, 1832; Monthly Journal of Medical Literature, 1832; New England Journal of Medicine and Surgery and Collateral Sciences, 1812; Worcester Journal of Medicine, 1845.

chusetts, was a man of learning and accurate observation, and an industrious and skilful practitioner. He died at the age of 100 years and 8 months. He was one of the principal founders of the Massachusetts Medical Society, and its first President. He published Astronomical observations, and articles in the Transactions of the Massachusetts Medical Society, and in the New York Medical Repository. (b. Aug. 1, 1728 (O. S.); d. 1829.) Dr. James Lloyd was the first surgeon in America to use ligatures, instead of searing wounds with the actual cautery, and to use the double flap in amputation. He also performed lithotomy. For nearly 60 years, he was the great physician and surgeon of New England. He was a warm advocate of inoculation for the small-pox. (b. April, 1728; d. March, 1810.) Dr. John Warren acquired much reputation as a hospital surgeon in the Revolutionary army. He was the head of a family of eminent physicians and surgeons of Massachusetts, and the brother of the patriot, Dr. and Gen. Joseph Warren. Dr. Warren was the earliest systematic teacher of Anatomy in Massachusetts, and the founder of the Medical Department of Harvard University, in which he held a chair up to the time of his death. He was President of the Massachusetts Medical Society, and a member of nearly all the learned societies of his time. He published observations on the "Mercurial practice," and contributed articles to the Transactions of the Massachusetts Medical Society, and of the American Academy of Arts and Sciences. (b. July 27, 1753; d. April 4, 1815.) Dr. J. Collins Warren, his son, was not inferior to his father. He was the first surgeon to use ether as an anæsthetic in surgical operations, and aided much to promote its use. He was also an author and teacher of great ability. (b. Aug. 1, 1778; d. May 4, 1815.) Dr. Benjamin Waterhouse, a native of Rhode Island, was, in 1799, the introducer of vaccination in America. He was a zealous and able defender of the practice of vaccination, and published two works upon the subject. He held the chair of Theory and Practice of Medicine, in Harvard College, from 1783 to 1812. He was a man of very active intellect and varied information, fond of study, and a voluminous writer. (b. March 4, 1754; d. Oct. 2, 1846.)

Dr. James Jackson, a native of Massachusetts, commenced practice in the year 1800. In 1810, with Warren and others, he initiated measures which led to the establishment of the McLean Asylum for the Insane, and also for the founding of the Massachusetts General Hospital. He was physician to the latter institution until 1835. In 1810, he was appointed clinical lecturer to Harvard College, and in 1812, to the chair of Theory and Practice. His contributions to the literature of medicine were numerous and valuable. (b. Oct. 3, 1777; d. Aug. 26, 1867.) Dr. John Ware, a native of Massachusetts, was from 1832 to 1858 Professor of Theory and Practice in Harvard College. He was a most admirable teacher, a close reasoner and original observer, and a beautiful and correct writer. (b. Aug. 1, 1778; d. May 4, 1854.) Dr. James Thacher, a native of Massachusetts, settled in practice in Plymouth, after having served as a surgeon in the Revolutionary army. During his military life, he kept a journal, which he subsequently published, and which has become a most valuable contribution to the history of the times. He was the author of the work entitled "The New Dispensatory," and of a number of other publications. His best known work is entitled "American Medical Biography," and is a great storehouse for information pertaining to the early profession in America. (b. 1754; d. May 24, 1844.) Dr. Elisha Bartlett, a native of Rhode Island, was a leading physician,

and the first Mayor of the city of Lowell. He was a close student and fine classical scholar. He was a sufferer from lead poisoning, but held professorships in quite a number of colleges. Although he wrote numerous works, his most popular one is on the fevers of the United States, published in 1842. (b. 1805; d. 1855.) Dr. Luther V. Bell, a native of New Hampshire, gained the Boylston Prize when about 30 years of age. By his ability in the treatment of the insane, he attracted the special attention of his contemporaries, and was placed in charge of the McLean Asylum, which continued under his control from 1837 to 1856. In 1857, he was President of the Massachusetts Medical Society. He wrote on many subjects of interest to the medical profession. During the late war, he went out as a surgeon and lost his life in the service of his country. (b. Dec. 1806; d. 1862.)

The following also deserve mention: Drs. John Brooks, Jeffries Wyman, H. H. Childs, A. A. Gould, George Hayward, Oliver Prescott, Lemuel Danforth, S. G. Howe, G. Darby, A. L. Peirson, C. T. Jackson, T. W. Harris, Enoch Hale, Winslow Lewis, and W. T. G. Morton, dentist and discoverer of the use of ether as an anæsthetic.

Michigan.[1]—Dr. Zina Pitcher, a native of New York, entered the army in 1822 as an assistant surgeon; was promoted to be full surgeon in 1832, and resigned in 1836, when he settled in Detroit. He was not only a good physician and surgeon, but an energetic and successful business man. He was mayor of the city, a faithful and intelligent manager of the school fund, and one of the founders of the State Insane Asylum. In 1856 he was honored with the presidency of the American Medical Association. (b. April 12, 1797; d. April 5, 1872.) Dr. Richard Inglis was a good classical scholar, full of information and energy, cheerful in the sick-room, and an agreeable companion in society. With the profession of the State he was exceedingly popular, and in 1869 was elected President of the State Medical Society. Mention should also be made of Drs. E. M. Clark and Porter, of Detroit; Robinson, of Palmyra; Robert Clark, of Monroe; Isaac C. Paddock, of Pontiac, and Denton and Brigham, of Ann Arbor.

Minnesota.[2]—Dr. Samuel Willey, a native of Massachusetts, after

[1] Michigan was admitted as a State in the Union in 1837. The earliest settlements within her territory were by the French, in the vicinity of Detroit, in the latter part of the seventeenth century. The lands are generally good and heavily timbered. The population as given by the census in 1870 was 1,187,234, about one-sixth of the people residing in towns and cities of over five thousand inhabitants. The same authority gives the number of physicians as 1034. Population and wealth have rapidly flowed into this State. From land grants by the United States a large educational fund has been established both for general education and colleges of a high grade. There are two medical colleges, a State Medical Society, formed in 1819, and publishing Transactions, and an efficient State Board of Health.

The following medical journals have been published in Michigan: Detroit Review of Medicine and Pharmacy, 1866; Michigan University Medical Journal, 1870; Peninsular Independent Medical Journal. 1858; Peninsular Journal of Medicine, 1873; Peninsular Journal of Medicine and Collateral Sciences, 1858.

[2] Minnesota was a part of the Louisiana purchase. This region was visited as early as 1650, the French having had posts in different parts along the Lakes. The United States government established, in 1819, a military post at Fort Snelling. In 1845 settlements began to be made, and immigration set in actively, and in 1859 a territorial form of government was organized. In 1853 Minnesota was admitted into the Union. The population as given by the United States Census of 1870 was 446,056, with about one-tenth living in towns of over five thousand inhabitants. There were then in the State 402 physicians. The population and wealth of Minnesota are steadily increasing. The State is fertile and well timbered, and is well situated as to commercial lines, by lakes, rivers, and railroads. A

graduating was for two years assistant physician in the State Lunatic Asylum, at Columbus, Ohio. In 1852 he settled in practice in St. Paul, and soon acquired a full business. In the fall of 1862 he was appointed pension surgeon and medical referee for the State. The organization of the State Medical Society was largely due to his efforts, as was that of the State Board of Health. He was twice elected president of the State Society, and in 1870 was one of the Vice-Presidents of the American Medical Association. (b. 1828; d. Nov. 21, 1872.) Dr. E. Herman Smith, a native of Connecticut, after serving a year as surgeon on the French steamer "Arago," settled at St. Paul, and soon acquired a fair business. He was accurate in diagnosis, and an expert in the use of the microscope. Dr. H. C. Hand, a native of New Jersey, settled in St. Paul in 1871, and formed a business relation with his brother, Dr. D. W. Hand, then in practice in that place. In 1872 he became editor and publisher of the Northwestern Medical and Surgical Journal, which he conducted with ability. He was one of the physicians to the St. Paul's City Hospital. (b. March 17, 1849; d. March 2, 1876.) Dr. Josiah S. Weiser, a native of Pennsylvania, located in 1855 at Shakopee, a settlement chiefly made up of Germans. He was induced to join Gen. Sibley's military expedition, as surgeon, in June, 1863, and was murdered by the Indians while holding a parley with them. The following deserve mention: Drs. N. B. Hill, A. E. Ames, J. K. Reiner, J. C. Jones, J. D. Ford, L. B. Smith, and G. T. Turner.

MISSISSIPPI.[1]—Dr. Samuel A. Cartwright, a native of Virginia, settled at Natchez, Miss., and was particularly successful in the treatment of fever, and of cholera, during the epidemic of 1832. He wrote a number of valuable papers. (b. Nov. 30, 1793; d. May 3, 1863.) Dr. Erasmus D. Fenner, a native of North Carolina, settled in 1832 at Clinton, where his ability obtained for him a good practice. In 1840 he removed to New Orleans, and in 1844, in connection with Dr. A. Heister, established the New Orleans Medical Journal. He was one of the original members of the American Medical Association, and a Professor in the New Orleans School of Medicine. In 1849 he commenced the publication of the Southern Medical Reports, which extended to two volumes. He also edited the New Orleans Medical News and Hospital Gazette. (b. 1807; d. May 4, 1866.) Dr. Allen Gillespie, a native of Tennessee, after graduating in medicine, served as an assistant surgeon in the army of the Southwest. In 1824 he removed to Mississippi, and in 1834 settled at Granada, where he spent his life in the active duties of his profession. He possessed in a high degree the qualities that go to make the successful physician. It is claimed that to him is due the credit of introducing the practice of giving large doses of quinia as an anti-pyretic in miasmatic fevers. After treating fevers in

State Medical Society, organized in 1855, publishes Transactions, and a State Board of Health is also in successful operation.

The following medical journal has been published in Minnesota: Northwestern Medical and Surgical Journal, 1870.

[1] Mississippi was admitted into the Union in 1817, having been erected into a territory with Alabama in 1798. It had been visited by De Soto in 1540, and by La Salle in 1682, but the first successful settlement by Europeans was at Natchez, in 1716, under Bienville. According to the United States Census in 1870 the population was 827,922, about one-tenth of the people living in cities of over five thousand inhabitants. There were at the same time 1511 physicians. The lands are generally low, alluvial, and subject along the water-courses to overflow. A State Medical Association, organized in 1856, publishes Transactions annually, and institutions for the care of unfortunates have been established.

this way for years, he made his views public in 1835. The use of quinia in large doses has been recommended by others, but only during the remission. (b. Aug. 18, 1801; d. 1869.) In addition to the above-named, I will mention Drs. Samuel B. Malone and Elvis McCrory.

MISSOURI.[1]—Dr. Wm. Beaumont, a native of Connecticut, entered the army as assistant surgeon in July, 1812, and resigned in 1839, and settled in the city of St. Louis. In 1825, while stationed at the military post Michilimackinac, he met the Canadian, St. Martin, who had received a wound which left an opening into the stomach, exposing in a measure the operation of that organ. The Doctor made a series of experiments upon the process of digestion, which he published in 1838. This is one of the most complete series of observations ever made on the living stomach. (b. 1785; d. April 25, 1853.) Dr. Charles A. Pope, a native of Alabama, settled in St. Louis in 1841. He was studious, energetic, and ambitious in his profession, and soon acquired a leading practice. He was elected to the chair of Anatomy and then to that of Surgery in the St. Louis University. His preference in practice was for surgery, and in this he was very successful. He was a fluent lecturer, and familiar with the history of the various surgical operations and procedures. He was surgeon to the St. Louis City Hospital. He identified himself with all movements calculated to advance the medical profession, and was President of the American Medical Association in 1854. (b. March 15, 1818; d. July 6, 1872.) Dr. M. L. Linton, a native of Kentucky, settled in practice in St. Louis in 1842. He was elected to the chair of Obstetrics in the St. Louis Medical College, and in 1844, was transferred to the chair of Theory and Practice. In 1843 he founded and edited the St. Louis Medical and Surgical Journal, the first medical periodical published west of the Mississippi River. He possessed high intellectual endowments and scientific culture, and wrote well, and on a great variety of subjects—medical, literary, religious, and scientific. He was a member of the Academy of Sciences, and contributed many papers to it. He had an extensive practice, and was widely known in the Southwest. (b. 1808; d. June 1, 1872.) Dr. B. F. Shumard, a native of Pennsylvania, commenced to practise in Kentucky, but became connected with one of the U. S. Government Pacific R. R. surveys and explorations. His scientific acquirements led him to be much employed in such pursuits. He removed to St. Louis in 1853. In 1860 he was engaged in a geological survey of the State of Texas, which was interrupted by the war, when he returned to St. Louis, and resumed the duties of his profession. He was elected to the chair of Obstetrics in the University of Missouri. He was President of the Academy of Sciences at the time of his death. (b. Nov. 24, 1820;

[1] Missouri, a part of the Louisiana purchase of 1803, was admitted as a State in the Union in 1821. Its earliest settlers were the French, who built a fort on the present site of the city of St. Louis as early as 1719. Another point of early settlement was at St. Genevieve. The population of Missouri in 1870 was 1,721,295, about one-fifth of the people living in towns and cities of over five thousand inhabitants. There were then in the State 3560 physicians. Missouri has a large school fund, and a successful system of free schools. There are four medical colleges. A State Medical Society, formed in 1850, publishes Transactions. Institutions for the care of unfortunates, sufficient for the wants of the people, have been established.

The following medical journals have been published in Missouri: Humboldt Medical Archives, 1867; Kansas City Medical Journal, 1871; Kansas City Medical and Surgical Review, 1860; St. Joseph Journal of Medicine and Surgery, 1859; St. Louis Medical Reporter, 1866; St. Louis Medical and Surgical Journal, 1845; St. Louis Probe, 1850.

d. April 14, 1868.) Dr. Lewis F. Linn, a native of Kentucky, settled in Genevieve in 1819. He served in the war of 1812, and after this took an active part in public affairs. He was a fluent and eloquent speaker. In 1827 he was elected to the Legislature, and in 1833 to the U. S. Senate, which office he held to the time of his death. (b. 1795; d. 1843.) I will also mention Dr. John H. Watters, of St. Louis, who was one of the earliest to write upon the theory of the Correlation and Conservation of Forces, Drs. J. N. McDowell, John A. Chambers, and John Edwards.

New Hampshire.[1]—Dr. Nathan Smith, a native of Massachusetts, first practised in Cornish, New Hampshire. He suggested the establishment of a Medical Department in connection with Dartmouth College, and in 1797 gave there a course of lectures. In 1798 he was appointed Professor in the Medical Department. He taught all the branches, and furnished all the apparatus needed in teaching until 1810, when he was joined by another professor. In a few years, by his genius and indomitable perseverance, fair classes attended this institution. In 1813 he was invited to the chair of Surgery in Yale College, which he accepted. He continued, however, to lecture at Dartmouth, at the Vermont University, and at Bowdoin College. His reputation as a surgeon had by this time become national. The credit of having first pointed out that dislocations of the hip and other joints should be reduced by manipulation, is due to Dr. Smith. In 1824 he published a particularly valuable essay on typhoid fever, in which he made a distinction between typhoid and malarial fevers. (b. 1762; d. 1829.) Dr. Amos Twitchell, a native of New Hampshire, was a close observer, and an indefatigable student. It seems to be well authenticated that he was the first to place a ligature on the common carotid artery, which he did six months before the occurrence of the case reported by Sir Astley Cooper. I can discover no publications of Dr. Twitchell, but he was in the habit of taking part in the discussions of the New Hampshire Medical Society. (b. 1781; d. 1850.) Dr. Josiah Bartlett, a native of Massachusetts, commenced to practise in Kingston, N. H., in 1750. His intelligence, high moral character, and ability, soon brought him a full share of professional business. From 1765 to the time of the Revolution he was annually chosen to the Legislature, and was a Lieutenant-Colonel in the State militia. In 1775 he was elected to Congress, and in 1776 was the first on the roll call to vote for the Declaration of Independence. He served as a Justice of the Supreme Court of the State, and was one of the originators and first President of the New Hampshire Medical Society. (b. 1729; d. 1795.)

Dr. Ammi R. Cutter, a native of Maine, served as surgeon in the Revolutionary war, and part of the time was Physician General to the Middle Department of the army. After the war he settled at Portsmouth, where he acquired a large practice, and was greatly esteemed throughout the State. For many years he was president of the State Medical Society. (b. 1735; d. 1820.) Dr. Matthew Thornton was a native of Ireland, and settled at Londonderry. He was a surgeon in the expedition in 1745 against Louisburg. In 1775 he was president of

[1] New Hampshire was one of the thirteen original States; its first settlement having been near Portsmouth, in 1623. Its population in 1870 was 318.300, nearly one-fifth living in cities and towns of over five thousand inhabitants. The number of physicians was 565. There is a State Medical Society, formed in 1791, which publishes Transactions annually, and one medical college. There are also institutions for the care of unfortunates, sufficient for the wants of the people.

the convention which assumed the government of New Hampshire in the name of the people. He was a delegate to Congress, and signed the Declaration of Independence, though not present to vote for it. (d. June 24, 1803, aged 88.) Dr. Lyman Spalding, a native of New Hampshire, began practice at Portsmouth in 1799. He was a good anatomist and a learned physician. He published in 1799 a new nomenclature of chemistry. In 1813 he removed to the city of New York. He conceived the idea of publishing a United States Pharmacopœia, and for years advocated the project, and called the convention which formed it in 1820, being also one of the committee of publication. (b. June 5, 1775; d. Oct. 31, 1821.) Dr. Dixi Crosby, a native of New Hampshire, commenced practice at Gilmanton, where he acquired a large business, and established his reputation as a surgeon. In 1836 he removed the scapula, humerus, and two-thirds of the clavicle at one operation, the patient recovering. In 1838 he was elected to the chair of Surgery and Obstetrics, in Dartmouth College, which position he held till 1868, when he resigned the branch of Surgery in favor of his son, lecturing for two years longer on Obstetrics. He contributed a number of able articles to the medical journals, and was President of the New Hampshire State Medical Society, and a member of the American Medical Association. (b. Feb. 9, 1800; d. Sept. 26, 1873.) I will also name Drs. Mathias Spaulding, Josiah Crosby, Charles P. Gage, W. Graves, Daniel Oliver, George B. Twitchell, and A. Smalley.

New Jersey.[1]—Dr. William Burnett, a native of New Jersey, settled in practice at Newark, and, during the Revolution, took a conspicuous part in the events of the day. He was a member of the "Committee of Safety," in 1776, and was one of the commissioners for issuing State bills of credit. He was physician of the hospitals, and Chief Surgeon of the State troops; and was a member of Congress from 1780 to 1781. In the latter year he was again elected to Congress, but resigned, and was appointed Chief Physician and Surgeon in the Eastern Department, serving till the close of the war. After peace was established he returned to private practice, and engaged to some extent in agriculture. He was Judge of the Court of Common Pleas and President of the State Medical Society, and throughout a long life was greatly beloved and esteemed. (b. 1730; d. 1791.) Dr. Moses Scott was a native of Pennsylvania, and on the outbreak of the Revolutionary war, took part with the patriots. He had been in military service with Braddock's expedition. In July, 1776, he was appointed physician and surgeon of the State troops, and in 1777, when Congress took entire control of the hospital department, was appointed Assistant Director General. He was present at all the battles fought in New Jersey. After the war he was esteemed one of the most experienced and learned physicians in the State. (b. 1738; d. 1821.) Dr. Jonathan Elmer, a native of New Jersey, was a surgeon in the

[1] New Jersey is one of the thirteen original States. The Dutch made two settlements at Bergen between 1614 and 1624, and a Swedish colony settled near the Delaware River in 1627. Some of the most stirring events of the Revolutionary war took place within the territory of New Jersey. Her position between the two great cities of New York and Philadelphia gives her great commercial advantages. Her population, as given by the census of 1870, was 906,096, a little over one-third of her people living in cities of over five thousand inhabitants. She had at the same time 1208 physicians. She has a State Medical Society, organized in 1766, which publishes Transactions annually. She has also a number of institutions for the care of unfortunates.

The following medical journal has been published in New Jersey: New Jersey Medical Reporter, 1847.

Revolutionary war, as was his brother Ebenezer. He was a man of extensive information, with great power of detail, and executive ability. He was elected to Congress in 1776, serving till 1778; again in 1781, serving till 1784; again in 1787, serving till 1788, and was United States Senator from 1789 until 1791. He was a member of the American Philosophical Society, and held many offices of trust in his native State. (b. 1745; d. 1817.) Dr. Nicholas Belleville, a native of France, settled in Trenton in 1791. He had a very extensive practice, and was physician to Joseph Bonaparte, ex-King of Spain, while he resided in New Jersey. His office was the resort of many students who subsequently rose to eminence in their profession. Dr. John N. Woodhull, a native of New Jersey, was a man of superior education. He settled at Princeton, and enjoyed the reputation through life of being a most skilful physician. He endowed a professorship in Princeton College. His whole life reflects honor upon himself, as a man, as well as upon the medical profession. (b. 1752; d. 1831.) Dr. L. A. Smith, a native of New Hampshire, was a physician of superior ability. He settled at Newark, and had the esteem of the profession, and was popular with the community. He was one of the early movers for, and an able advocate of, the establishment of the New Jersey Lunatic Asylum. He was devoted to his profession, and was an earnest promoter of medical organizations. He was President of the New Jersey State Medical Society, in 1837, and throughout his life was an active worker for the advancement of medicine and the elevation of the profession. (b. Nov. 11, 1795; d. Dec. 15, 1865.) The following names are also deserving of mention: Drs. John Beatty, W. Johnson, Isaac Ogden, Samuel Hayes, J. Ward, Isaac P. Coleman, Silas Condit, Isaac Pierson, and J. Lilley.

New York.[1]—Dr. Valentine Mott, a native of New York, and an

[1] New York is one of the thirteen original States. Its earliest known mention was in 1609, from the visit of Henry Hudson, who gave his name to the Hudson River. This is now the most populous and wealthy State in the Union. The population in 1870 was 4,387,464, nearly one-half living in cities of over five thousand inhabitants. The number of physicians in the same year was 6810. New York has nine medical colleges, distributed as follows, viz.: Albany, Brooklyn, Buffalo, and Syracuse, each one, and New York City five. A State Medical Society was organized in 1807, and has published Transactions almost continuously since. Institutions for the care and treatment of unfortunates have been provided in different parts of the State, sufficient for the wants of the people.

The following medical journals have been published in New York: Albany Journal of Neurology, 1843; American Chemist, 1870; American Journal of Indigenous Materia Medica and Repertory of Med. Science, 1860; American Journal of Insanity, 1844; American Journal of Medicine, 1852; American Journal of Obstetrics and Diseases of Women and Children, 1868; American Journal of Ophthalmology, 1862; American Journal of Syphilography and Dermatology, 1870; American Lancet, 1831; American Medical Monthly, 1854; American Medical and Philosophical Register, 1810; American Medical and Surgical Journal, 1851; American Medical Times, 1860; Annalist, 1847; Archives of Ophthalmology and Otology, 1869; Archives of Scientific and Practical Medicine, 1873; Buffalo Medical Journal, 1845; Buffalo Med. and Surgical Reporter, 1861; Medical Gazette, 1867; Medical Record, 1866; Medical and Surgical Register, 1818; Nelson's American Lancet; New York Journal of Medicine, 1839; New York Journal of Medicine and Collateral Sciences, 1843; New York Journal of Pharmacy, 1852; New York Lancet, 1842; New York Medical Gazette, 1841; New York Medical Gazette and Journal of Health, 1850; New York Medical Independent and Pharmaceutical Reporter, 1864; New York Medical Inquirer and Domestic Magazine, 1830; New York Medical Journal, 1831; New York Medical Journal, 1865; New York Medical Magazine, 1814; New York Medical and Pathological Journal, 1858; New York Medical and Philosophical Journal and Review, 1809; New York Medical and Physical Journal, 1822; New York Medical Press, 1860; New York Medical Repository, 1797; New York Medical Review, 1873; New York Medical and Surgical Reporter, 1845; New York Medical Times, 1851; New York Medico-Chirurgical Bulletin, 1851; New York

eminent surgeon and teacher, settled in New York City in 1809, and was appointed to the chair of Surgery in Columbia College. He was elected to fill the same chair in Rutgers College, and also in the College of Physicians and Surgeons. In 1818 he passed a ligature around the brachio-cephalic artery, about two inches above the heart, for aneurism. He excised the entire clavicle, and was the first in America to ligate the iliac artery, and to remove the lower jaw. Sir Astley Cooper says of him, that he performed more of the great operations than any other surgeon, living or dead. It would be impossible to enumerate here all his great achievements. In 1814, in connection with Dr. Onderdonk, he started and published the "New York Medical Magazine," which only extended to two parts. He translated Velpeau's work on Surgery, and contributed articles to the medical journals, and to the Transactions of the New York Academy of Medicine. (b. Aug. 20, 1785; d. April 26, 1865.) Dr. Samuel Bard commenced practice in 1767 in the city of New York. He was one of the projectors of the first Medical College organized in New York, and held the chair of Theory and Practice. He acted as examining surgeon for the admission of surgeons to the Medical Department of the Army during the Revolutionary war. In 1774, he was influential in founding the New York Hospital, in which he gave a course of clinical lectures. In 1791, when the public hospital was opened, he was appointed one of the visiting physicians. In 1798, he had retired to his country seat, but on the outbreak of the yellow fever returned to the city, and resumed practice. He was finally taken down with the fever, but recovered. He was General Washington's physician, when in New York, after the war. He published a compendium of Midwifery, and contributed to the Philosophical Transactions and to medical journals. (b. April 1, 1742; d. May 24, 1821.)

Dr. David Hosack, a native of New York, settled in practice in the city of New York in 1794. The following year he was appointed Professor of Botany in Columbia College, and shortly afterwards published a syllabus of the lectures. In 1796, he formed a partnership with Dr. Bard, which continued till 1800. In 1797 he was elected to the chair of Materia Medica, but in 1811, on the re-organization of the Faculty, was assigned to the chair of Theory and Practice, and afterwards held that of Obstetrics and Diseases of Women and Children, until 1826. He was visiting physician to the Almshouse and to the Insane Asylum. He wrote on fevers, and other medical topics, and was elected a member of the Royal Society of London. His paper on the causes of contagion was able, and received a wide appreciation. In 1810, with Dr. Francis, he started the American Medical and Philosophical Register, which was conducted with ability. (b. August 31, 1769; d. Dec. 22, 1835.) Dr. Theodoric Romeyn Beck, a native of New York, began practice in Albany in 1811. In 1813 he wrote a paper on the minerals of the United States. In 1815 he was appointed Lecturer on the Institutes of Medicine, and Professor of Medical Jurisprudence in the College of Physicians and Surgeons. He also held a professorship in the Fairfield Medical College from 1826 to 1836. In 1836 he was elected to the chair of Materia

Monthly Chronicle of Med. and Surg., 1824; New York Monthly Review of Med. Science and Buffalo Medical Journal; New York Register of Medicine and Pharmacy, 1850; North American Medical Reporter, 1858; Northern Lancet and Gazette of Legal Medicine, 1850; Opal, 1851; Quarterly Journal of Psychological Medicine, 1867; Sanitarian, 1873; Syracuse Medical and Surgical Journal, 1854; United States Medical and Surgical Journal, 1834.

Medica in the Albany Medical College. From 1840 to 1850 he was President of the Albany Academy, and was the originator of the Albany Institute. He was President of the New York State Medical Society, and was one of the managers of the State Lunatic Asylum. In 1823 he published the first edition of his great work on "Medical Jurisprudence." He edited for some years the "American Journal of Insanity." (b. Aug. 11, 1791; d. Nov. 19, 1855.) Dr. J. W. Francis, a native of New York, commenced to practise in 1811, and formed a partnership with Dr. Hosack. They together published the American Philosophical Register. In 1813 he was lecturer in the Institute of Medicine, and Professor of Materia Medica in the College of Physicians and Surgeons. About this time he visited Europe, and on his return was elected to the chair of Medical Jurisprudence, and in 1819 filled that of Obstetrics, in Rutgers College. In 1822 he was one of the editors of the New York Medical and Physical Journal. He was an accomplished writer, and took an active part in promoting the objects of the New York Academy of Medicine, the Historical Society, the Woman's Hospital, etc. (b. Nov. 17, 1789; d. Feb. 8, 1861.)

Dr. A. H. Stevens, a native of New York, commenced practice in the city of New York in 1812. In 1814, he was invited to the chair of Surgery in Queen's, afterwards Rutgers College. He was one of the visiting surgeons to the New York Hospital. In 1817, he was assigned to a chair in the College of Physicians and Surgeons. In 1848, he was President of the New York State Medical Society, and also President of the American Medical Association. His general as well as his surgical practice was very large. His contributions to the literature of medicine are found in Journals, Reports, and Addresses. (b. 1789; d. March 30, 1869.) Dr. Wright Post, a native of New York, commenced practice in 1786. The chair of Surgery in Columbia College was tendered him in 1792, but in 1793 he was transferred to the chair of Anatomy, which he continued to hold for twenty years. He was also a member of the Faculty of the College of Physicians and Surgeons, and its president from 1821 to 1826. He was for thirty years consulting physician of the New York Hospital. He was a bold, original, and successful operator. He tied the subclavian artery, and also the carotid. (b. Feb. 19, 1766; d. June 14, 1828.) Dr. John Torrey, a native of New York, although a learned physician, never acquired a large practice, and being greatly interested in botany and the collateral sciences, his time became occupied by them. In 1817, he published a catalogue of plants growing within thirty miles of New York city, and in 1831 published the first volume of the Flora of North America. In 1824 he was appointed Professor of Botany in the Military Academy at West Point, and from 1827 to 1850 was Professor of Chemistry in the College of Physicians and Surgeons of New York. He was subsequently appointed director of the New York Assay Office. The Doctor was one of the most accomplished botanists of our country, and did much to elevate the science by his life and teachings. (b. 1798; d. March 10, 1873.)

Dr. Samuel L. Mitchell, a native of New York, commenced practice in New York city, and, with Dr. E. Miller and Dr. E. H. Smith, started, in 1797, the "New York Medical Repository." He was connected with it as editor for sixteen years, and survived both of his associates. He was a member of the State Legislature, and for a number of years a member of Congress, and also U. S. Senator. He was a man of very extensive scientific acquirements, and of a remarkably retentive memory. He

wrote on a variety of topics. making substantial additions to scientific literature. (b. Aug. 20, 1764; d. Sept. 7, 1831.) Dr. Joseph M. Smith, a native of New York, commenced practice in 1811. He was one of the original members of the Medico-Philosophical Society, which published its first volume in 1817. He was Professor of Theory and Practice in the College of Physicians and Surgeons for thirty years. His most noted work is perhaps his "Elements of Etiology, and Philosophy of Epidemics." He was a frequent and valued contributor to medical serial literature. (b. March 14, 1789; d. April 22, 1866.) As of almost equal merit, I will name Drs. John Watson, J. Kearney Rodgers, J. Stearns, Joseph White, Richard Bayley, W. W. Reid, John A. Smith, Charles A. Lee, Alden March, John B. Beck, James Stuart, Elisha Smith, H. D. Bulkley, John A. Swett, Amasa Trowbridge, Amariah Brigham, George T. Elliot, James McNaughton, H. Green, J. H. Armsby, Alban Goldsmith, R. S. Kissam, and H. M. Onderdonk.

North Carolina.[1]—Dr. Charles Harris, a native of North Carolina, served in the Revolutionary war before he had completed his medical education. He first practised with success at Salisbury, but removed to Favonia, the name of his plantation in Cabaries County, where he remained actively engaged in practice to the close of his life. Ninety-three physicians studied with him, his reputation being such as to make him a desirable preceptor. His professional life extended over forty years. (b. 1763; d. Sept. 21, 1825.) Dr. James Norcom, a native of North Carolina, commenced practice at Edenton in 1799. He acquired a large but laborious business, often visiting patients at a distance of 100 miles, on horseback. His practice was chiefly that of a physician, although performing such surgical operations as usually fall to the lot of rural practitioners. His obstetrical practice was large. In 1812, he was commissioned Assistant Surgeon in the U. S. Army, but resigned in January, 1813. He wrote a paper on the Winter Epidemic of 1816, and made a number of contributions to medical journals. (b. 1788; d. Nov. 9, 1850.) Dr. James Dickson, a native of North Carolina, having practised for a couple of years in South Washington, removed to Fayetteville, where his practice became large. In 1835, he performed successfully the operation of transfusion of blood. In 1828, 1831, and 1833, he performed urethrotomy. In 1835, he divided the tendo Achillis, for the relief of club-foot. About this time he ligated the external iliac artery. He was everywhere recognized as a skilful and successful surgeon. Dr. Benjamin Robinson, a native of Vermont, commenced practice in his native place, but removed to North Carolina in 1804, and settled at Fayetteville, where he spent the remainder of his life, laboriously engaged in

[1] North Carolina is one of the thirteen original States. Sir Walter Raleigh attempted to establish a colony in it in 1585, but failed. The earliest point successfully settled was on the Roanoke and Chowan Rivers, by emigrants from Virginia, in 1653. In 1693, North and South Carolina were separated. This State took an early and active part to secure American Independence. Ephraim Brevard, at a meeting of the citizens at Charlotte, on May 20, 1775, prepared what is known as the "Mecklenburg Declaration of Independence." This embodied many of the sentiments of the Declaration adopted more than a year later, at Philadelphia. The population of the State, as given by the census of 1870, was 1,071,362. There are no large cities or towns, and but about one in forty of the population live in towns of over five thousand inhabitants. There were, in 1870, 1143 physicians. A medical college has been projected, but is not yet organized. There is a State Medical Society, formed in 1850, which publishes Transactions. Institutions for the care of unfortunates, sufficient for the wants of the people, have been provided.

The following medical journal has been published: Medical Journal of North Carolina, 1858.

his profession. While a student of medicine, he performed an operation for the relief of strangulated hernia, with success. He was distinguished through life for his untiring assiduity and sound common sense. His memory is still cherished by the descendants of the community in which he passed his useful life. (d. March 8, 1857, aged 82.) Dr. Charles E. Johnson, a native of North Carolina, settled in practice at Edenton, and thence removed to Raleigh in 1835. He was especially interested in nervous diseases and physiological studies. He wrote a paper on the Medico-Legal Relations of Insanity. (b. March 15, 1812; d. April 1, 1876.) Dr. Armand John De Rosset was a native of North Carolina, and a graduate of Princeton College. His immediate ancestors, father, grandfather, and great grandfather, were physicians. The duration of his practice extended to 69 years. He was a good classical scholar, and a cultivator of the sciences, which he applied to the practical and every-day requirements of his profession. (d. April 1, 1859, æt. 92.) I will also mention Drs. James J. Philips, of Edgecombe Co.; James Furgus McRee, of Wilmington; R. H. Shield, of Winton; Wm. H. McKee, of Raleigh; Wm. Perry, of Franklin Co.; Elisha Battle, of Edgecombe Co.; Henry M. Shaw, of Kurrituck Co.; Joel B. Houston, of Columbia; Matthias E. Sayer, of Edenton; Simon J. Baker, of Raleigh; and Pinckney Caldwell.

OHIO.[1]—Dr. Daniel Drake, a native of New Jersey, but reared in Kentucky, began to practise in Cincinnati in 1804. He rapidly rose to be recognized as a leading physician, and as one of very extensive knowledge and scientific attainments. In 1810 he published "Notes" concerning Cincinnati, and in 1815 a work entitled "A Picture of Cincinnati." In 1817 he was elected a professor in the Transylvania University, at Lexington, Ky. The following year he obtained a charter and founded the Medical College of Ohio, at Cincinnati, and in 1819 he established the Commercial Hospital. From 1827 to 1839 he edited the "Western Journal of American Medical Sciences." Its publication was transferred to Louisville, Ky., and the name changed to "Western Journal of Medicine and Surgery." He continued as one of the editors till 1848. In 1832 he published an essay on Medical Education and Medical Men of the United States, and the same year a pamphlet on Cholera. His great work, which contained the observations of nearly half a century, was published in 1850, entitled "Diseases of the Interior Valley of

[1] No European settlement prior to the Revolution is known to have been made in Ohio. The first emigration to this State was in 1788, from New England to a point known as Marietta, on the Ohio River, it having been included in 1781 in the general territorial legislation pertaining to the territory northwest of that stream. The population in 1870, as given by the U. S. Census, was 2,605,260, nearly one-fourth of the population living in towns of over five thousand inhabitants. There were at that time 4638 physicians. Population and wealth are still rapidly accumulating in this State. It has seven medical colleges, three at Cincinnati, two at Cleveland, and two at Columbus. A State Medical Society was established in 1846, and publishes reports annually. Institutions for the care of unfortunates have been provided, sufficient for the wants of the people.

The following medical journals have been published in Ohio: Annals of Science, 1853; Cincinnati Journal of Health, 1844; Cincinnati Journal of Medicine, 1869; Cincinnati Lancet and Observer, 1858; Cincinnati Medical News, 1858; Cincinnati Medical News, 1872; Cincinnati Medical Observer, 1856; Cincinnati Medical Repertory, 1868; Cincinnati Medical and Surgical News, 1860; Cleveland Medical Gazette, 1859; Clinic, 1871; Columbus Review of Medicine and Surgery, 1860; Critic, 1853; Northern Ohio Medical and Scientific Examiner, 1848; Ohio Medical Recorder, 1876; Ohio Medical Repository of Original and Selected Essays and Intelligence, 1826; Ohio Medical and Surgical Journal, 1848; Ditto, 1876; Western Journal of Medical and Physical Sciences, 1828; Western Journal of Medicine, 1840; Western Lancet, 1842; Western Medical Gazette, 1832; Western Quarterly Reporter of Medical, Surgical, and Natural Science, 1822.

North America." A second volume of this series, in preparation at the time of his death, was published subsequently. This great work deserves to be better known. (b. Oct. 20, 1785; d. Nov. 6, 1852.) Dr. Reuben D. Mussey, a native of New Hampshire, commenced practice in Essex Co., Massachusetts, in 1805, after having received the degree of Bachelor of Medicine from Dartmouth College. In 1807 he attended lectures at the University of Pennsylvania, and wrote a thesis on Cutaneous Absorption, based upon original observations, his experiments proving certain facts, while an opposite doctrine was being taught in the colleges. He made many other experiments upon this subject, which have not been published. Fresh from the college at Philadelphia, he settled at Salem, Mass., where he obtained a good practice, and where he resided for six years, devoting much time to the surgery of the eye. In 1814 he was elected to the chair of Theory and Practice in Dartmouth College, and in 1819 to the chair of Anatomy and Surgery in the same institution, holding the latter position till 1838. He also gave lectures on chemistry at Middlebury College, and at Fairfield College, New York. In 1829 the doctor visited Paris, to study medical institutions abroad. During the year 1837 he was tendered three professorships, at Nashville, New York, and Cincinnati, and accepted the latter. His fame as a surgeon preceded him, and in a few years he was one of the best known surgeons in the Valley of the Mississippi. He possessed much mechanical skill, and had a genius for original operations. He performed many capital and heroic operations, tying on the same patient within twelve days both carotid arteries, and saving his patient's life. His whole professional life was one of eminent success, and sheds lustre upon the profession. He was President of the American Medical Association in 1850. (b. 1780; d. 1866.)

Dr. John Delemater, a native of New York, commenced practice in 1809, in the city of New York. He subsequently practised in Pittsfield, Mass., and was connected with the Medical College there. In 1843 he removed to Cleveland, Ohio, and was elected to the chair of General Pathology and Midwifery in the Western Reserve College at that place. (d. April, 1867, aged 80.) Dr. George Mendenhall, a native of Pennsylvania, commenced practice in Cleveland, but in 1843 removed to Cincinnati, where by great devotion to his profession he acquired a large business. In 1852 he was elected to the chair of Obstetrics in the Miami Medical College, and, on the consolidation of that college with the Medical College of Ohio, was re-elected and continued to serve till his death. He published a "Vade Mecum," which passed through several editions. He was one of the editors of the "Western Lancet," and afterwards of the "Lancet and Observer." The journals contained many articles from his pen. He was President of the American Medical Association in 1870. (b. 1814; d. 1874.) Dr. Jesse P. Judkins, besides having a large practice, was Demonstrator of Anatomy in the Ohio Medical College, and Professor of Anatomy in Starling Medical College, at Columbus. Afterwards he held the chair of Special Pathology in the Miami Medical College, filling the latter position with ability up to the time of his death. He wrote a number of excellent papers which were published in the Cincinnati Medical Journal. (d. Dec. 6, 1867, aged 52.) Dr. Horace Ackley settled in practice at Akron. He was elected professor in Willoughby College in 1837. In 1843 he was elected Professor of Surgery in the College then at Cleveland. He was an early and efficient member of the Ohio State Medical Society, and for some years its president. He

was physician to the Marine Hospital at Cleveland, and one of the trustees for the Central and Southern Lunatic Asylums. His surgical practice was for years quite large, and he was esteemed a safe and skilful operator. (d. April 22, 1859, æt. 47.)

Dr. Leonidas M. Lawson, a native of Kentucky, first practised in Madison, and started the "Western Lancet;" and in 1844, commenced the reprint of Hooper's Pathological Anatomy. The same year he was invited to a chair in the Transylvania University. In 1845 he visited England and France, to study medical institutions abroad. In 1847 he was offered the chair of Materia Medica and Special Pathology in the Medical College of Ohio. He also at this time held chairs in the Kentucky School of Medicine and in the University of Louisiana. (d. Jan. 21, 1864, æt. 51.) Dr. John Dawson, a native of Virginia, after practising for some time in Green County, removed in 1851 to Columbus, and in 1853 was elected to the chair of Anatomy in the Starling Medical College. As a teacher he gave great satisfaction to his associates and to the students. About this time he became editor of the Ohio Medical and Surgical Journal. He was an original observer and forcible writer. (d. Sept. 1866, æt. 55.) Dr. G. W. Boerstler, a native of Maryland, settled in practice in Lancaster, 1853. All the sympathies and all the energies of his nature were directed to the discharge of his duties as a physician. His practice was very large. (d. Oct. 19, 1871, æt. 78.) Dr. George C. Blackman, a native of Connecticut, commenced to practise in the State of New York, where he acquired reputation as a surgeon. In 1854 he was elected to the chair of Surgery in the Medical College of Ohio. He was surgeon to the Cincinnati Hospital, and also to the Good Samaritan Hospital. On the breaking out of the war he entered the medical service of the army as a Surgeon of Volunteers. He was a man of fine presence, and had an air of resolution. (d. July 19, 1871.) I will name in addition, Drs. Edward Tiffin, John P. Harrison, John Butterfield, G. F. Mitchell, R. L. Howard, Daniel Tilden, Philip J. Buckner, John T. Shotwell, J. W. Russell, and S. M. Smith.

PENNSYLVANIA.[1]—Dr. Benjamin Rush commenced practice in Philadelphia in 1769, and the same year was elected to the chair of Chemistry

[1] Pennsylvania is one of the thirteen original States, and was settled by the benevolent William Penn in 1682. This State took an active part in the measures that ushered in the struggle for American Independence, and was, during the war, the chief seat of Congress. On her territory were fought several of the important battles of the Revolution. The population in 1870, according to the U. S. Census, was 3,522,050, nearly one-third living in towns of over five thousand inhabitants. The number of physicians at the same time was 4843. There are three medical colleges, all in Philadelphia. There is a State Medical Society, formed in 1848, which publishes a volume annually. Institutions for the insane and other unfortunates have been provided in different parts of the State. Pennsylvania has from the settlement of our country taken the lead in matters relating to medical publication and medical education, and, as a consequence, we find, as would be expected, a larger proportion than usual of eminent medical men resident within her borders.

The following medical journals have been published: Æsculapian Register, 1824; American Journal of the Medical Sciences, 1827; American Journal of Pharmacy, 1825; American Library and Intelligencer, 1836; American Medical Intelligencer, 1837; American Medical Recorder, 1818; Barrington & Haswell's Medical Bulletin, 1849; Bulletin of Medical Science, 1843; Cholera Gazette, 1832; Compendium of Medical Science, 1868; Hospital Register, 1863; Journal of the Philadelphia College of Medicine, 1829; Medical Examiner, 1838; Medical Reporter, 1853; Medical Review and Analectic Journal, 1826; Medical and Surgical Reporter, 1856; Medical Times, 1870; North American Medical and Surgical Journal, 1826; Philadelphia Journal of Medicine and Physical Sciences, 1820; Philadelphia Medical Museum, 1805; Philadelphia Medical and Physical Journal, 1804; Philadelphia Medical and Surgical Journal, 1853; Philadelphia Monthly Journal of Medicine and Surgery, 1828.

in the Philadelphia College. In 1787 he was assigned to the chair of Theory and Practice. He possessed a remarkably well trained and observing mind, and, in addition to his professional duties, took an active part in all public affairs. He was for many years physician to the Pennsylvania Hospital and other benevolent institutions. In the State convention he moved that the colony should express its sentiments on the subject of separation from the mother country. He was shortly afterwards elected to Congress, and signed the Declaration of Independence. His writings embrace many topics in medicine, and are everywhere characterized by originality and ability. His conduct through life as a citizen and physician was such as to make him a marked man. (b. Dec. 24, 1745; d. April 19, 1813.) Dr. Philip Syng Physick, a native of Pennsylvania, commenced to practise in Philadelphia in 1793, after having spent a number of years in visiting the hospitals of Europe. This was the year of the great yellow fever epidemic in Philadelphia. Dr. Physick was placed in charge of Bush Hill Hospital, and discharged his duties with marked ability. In 1794 he was appointed one of the surgeons of the Pennsylvania Hospital, and from 1801 to 1816 he was one of the consulting surgeons of the Philadelphia Almshouse Infirmary. In 1815 he was appointed Professor of Surgery in the University of Pennsylvania, in which he afterwards filled the chair of Anatomy. In 1825 he was elected a member of the Royal Academy of Medicine of France, and in 1836 a member of the Royal Medical and Chirurgical Society of London. (b. 1768; d. Dec. 15, 1837.) Dr. John Morgan, a native of Pennsylvania, after serving as surgeon to the Militia in the French war in 1759, resigned in 1760, and went to Europe to further perfect his knowledge of medical science. He returned to Philadelphia in 1765, and was then perhaps the most learned physician in America. The same year he delivered an address at the commencement of the Philadelphia College, and the opening of the first medical college in America, established through his own and Dr. William Shippen's influence, and in which he was appointed Professor of Theory and Practice. In 1775 Dr. Morgan was appointed Director General and Physician in Chief of the Hospital Department of the American Army, but political cabals and the exigencies of the times caused his removal in 1777. A report by Congress shows him to have been an efficient officer. In his thesis he proposed the theory that pus was formed by a secretory process. He was one of the founders of the American Philosophical Society, and a member of the Royal Philosophical Society of London. (b. 1735; d. Oct. 15, 1789.)

Dr. Benjamin Smith Barton, a native of Pennsylvania, settled in practice in Philadelphia in 1789. He was the same year appointed Professor of Natural History and Botany, and in 1813 Professor of Materia Medica in the University of Pennsylvania. He contributed papers to the American Philosophical Society, and in 1804, started the "Medical and Physical Journal." He was an indefatigable worker, and all his writings were practical contributions to medicine. (b. Feb. 10, 1766; d. Dec. 19, 1815.) Dr. Caspar Wistar, a native of Pennsylvania, commenced practice in Philadelphia in 1787. In 1789 he was elected Professor of Chemistry and Physiology in the University of Pennsylvania. In 1792 he was elected physician to the Philadelphia Dispensary, and to the Pennsylvania Hospital, and the same year was appointed Adjunct Professor of Anatomy, which position he filled until the time of his death. His abilities as a physician secured him a large practice, and assisted in popularizing the school. He was a member of

many learned societies, and President of the American Philosophical Society. His best known work is his "Anatomy," in two volumes, the first of its kind contributed by an American. (b. Sept. 13, 1761; d. July 22, 1818.) Dr. Wm. P. Dewees, a native of Pennsylvania, commenced practice in the interior of the State, but removed to Philadelphia in 1793. He devoted his time chiefly to Obstetrics, but, his health failing in 1812, he retired to his farm at Phillipsburg, where he remained for five years, when, having recovered, he returned and resumed practice, which he continued with increasing popularity. In 1825 he was chosen assistant professor of Midwifery in the University of Pennsylvania, and in 1834 was elected to the full chair. But his health had gradually failed, and the following year he resigned and was elected emeritus professor. (b. May 5, 1768; d. May 20, 1841.) Dr. Nathaniel Chapman, a native of Virginia, commenced practice in Philadelphia in 1804. By his assiduity in professional duties, and by a fortunate marriage, he speedily acquired a large business. About this time he commenced a course of lectures on Obstetrics to medical students, and in 1808 associated himself with Professor James in a summer course of lectures. From 1813 to 1816 he was Professor of Materia Medica in the University of Pennsylvania, and from 1816 to 1850, Professor of Theory and Practice and of Clinical Medicine. In 1817 he founded the Medical Institute, and lectured in it during every summer for twenty-five years. He was President of the American Philosophical Society from 1846 to 1848, and President of the American Medical Association in 1847. (b. May 28, 1780; d. Jan. 1, 1853.) Dr. Wm. E. Horner, a native of Virginia, having resigned his commission in the U. S. Navy, commenced practice in the city of Philadelphia. His abilities soon attracted the attention of the leading physicians, and he shortly after received the appointment of Demonstrator of Anatomy in the University of Pennsylvania. In 1819 he was made adjunct, and in 1831 full Professor of Anatomy. In 1824 he discovered the "Musculus Horneri," which had escaped the observation of previous anatomists. His whole life was a continuous struggle of mind and duty over physical suffering. In 1847 he founded St. Joseph's Hospital, to which he bequeathed his library and instruments. About this time he published a treatise on Pathological Anatomy, which was shortly afterwards followed by other important publications. (b. Jan. 3, 1793; d. March 13, 1853.)

Dr. John K. Mitchell, a native of Virginia, settled in practice in Philadelphia in 1822, and soon acquired a large practice. After taking his medical degree he made three voyages to China as surgeon in a merchant ship. In 1824 he delivered a course of lectures on the Institutes of Medicine and Pathology before the Philadelphia Institute, and in 1826 was appointed to the chair of Chemistry and Applied Arts in the Franklin Institute. He was a ready writer, and frequently contributed to the medical journals. In 1841 he was elected to the chair of Theory and Practice in Jefferson Medical College, a position he filled with rare ability till the time of his death. He was a gifted lecturer, and occasionally introduced experiments with good effect, as he was an expert manipulator. His writings were numerous, and always contained important additions to medical knowledge. (b. March 12, 1796; d. April 4, 1858.) Dr. George McClellan, a native of Connecticut, shortly after graduation commenced practice in the city of Philadelphia. In 1825, with a few able associates, he founded the Jefferson Medical College, in which he was a professor till 1838. In 1839 he organized the Medical

Department of Pennsylvania College, from which he retired in 1844, and devoted his time to private practice. He was a fluent and agreeable lecturer. For a time he edited a medical journal in connection with Dr. John Eberle, and was a frequent contributor to the columns of periodical medical literature. (b. Feb. 22, 1796; d. May 9, 1847.) Dr. Robley Dunglison, a native of Scotland, was invited to the United States in 1824, and elected Professor of Medicine in the University of Virginia, where he continued till 1833. From 1833 to 1836 he was Professor of Materia Medica and Therapeutics in the University of Maryland, and from 1836 to 1868 was Professor of the Institutes of Medicine and Medical Jurisprudence in the Jefferson Medical College. His Medical Dictionary is by far the most convenient work of the kind known to the profession. (b. June 4, 1798; d. April 1, 1869.) Dr. T. D. Mütter commenced practice in Philadelphia about 1831, and shortly afterwards established a "Quiz class," and soon became a teacher of surgery in what was known as "Chapman's Medical Institute." He was made Adjunct Professor of Operative Surgery in Jefferson Medical College to assist Dr. Randolph, and on the resignation of the latter, was elected to the full chair of Surgery. It was in this field that he acquired his great reputation as a teacher and as an operator in rhinoplastic surgery. He has left an enduring monument to his name in the establishment of the "Mütter lectureship" and the "Mütter Museum" of the College of Physicians. Besides the names already given, I will mention Drs. William Shippen, Samuel Jackson, Franklin Bache, T. S. James, P. S. Dorsey, H. L. Hodge, C. D. Meigs, J. D. Godman, Adam Kuhn, J. Redman Coxe, Robert Hare, Samuel G. Morton, Réné La Roche, W. Darlington, John S. Parry, Samuel Jackson (of Northumberland), Peter Mowry, Nathaniel Bedford, James Agnew, Joseph Gazzam, B. R. Reese, W. W. Gerhard, Jacob Randolph, David Gilbert, G. W. Norris, Thomas T. Harrison, Joseph Parrish, Thomas Harris, and P. B. Goddard.

RHODE ISLAND.[1]—Dr. Isaac Senter, a native of New Hampshire, served as a surgeon in the Revolutionary war, and in 1779 settled in practice in Pawtucket. In 1780 he was appointed Surgeon and Physician-General to the State troops, and removed to Newport, where he passed the remainder of his life actively engaged in the practice of his profession. He contributed articles on medical subjects to the journals, and was an honorary member of the Massachusetts Medical Society, of the Medical Society of London, and of the College of Physicians of Philadelphia. He was for some years President of the Rhode Island State Medical Society. (b. 1735; d. Dec. 20, 1799.) Dr. Pardon Bowen, a native of Rhode Island, served during the Revolutionary war as a surgeon on a privateer, and in 1779 was taken prisoner, and after being exchanged re-entered the service. He settled in practice in his native town, and gradually acquired a large business. He was an active and efficient member of the Rhode Island State Medical Society, and for some years its president. He was also a member of the Board of Trustees of Brown University. His profes-

[1] Rhode Island is one of the thirteen original States. Its first settlement was in 1636 by Roger Williams, at the present site of Providence. Other settlements were soon made at Newport and at Warwick. The population in 1870, according to the United States Census, was 317,353. Nearly one-half of the people live in cities and towns of over five thousand inhabitants. The number of physicians in 1870 was 260. One medical college, a department of Brown University, is giving instruction. Rhode Island has a State Medical Society, formed in 1812, which publishes Transactions annually, and a good system of registration of vital statistics. Institutions for the care of the insane and other unfortunates have been established, sufficient for the wants of the people.

sional life extended to nearly half a century. (b. 1757; d. Oct. 25, 1826.) Dr. Usher Parsons, a native of Maine, became on graduating a surgeon in the navy during the war of 1812, and was in the battle of Lake Erie. After ten years' service he resigned, and settled in practice in Providence. He held a professorship in Brown, Jefferson, and other medical colleges, and was President of the Rhode Island Medical Society, and Vice-President of the American Medical Association. He wrote a number of medical works, and took four Boylston prizes. He was an influential promoter of the establishment of the Rhode Island Hospital, and a most agreeable and witty writer. (b. Aug. 18, 1788; d. Dec. 19, 1868.)

Dr. Solomon Drowne, a native of Rhode Island, served as a surgeon's mate in the Revolutionary war, and on the restoration of peace settled in Providence. In 1788 he joined a party going to the new settlement in the West, at Marietta, on the Ohio River. He attended, during his last illness, General Varnum, one of the Ohio Land Company, and, at the request of the community, pronounced his funeral eulogy. He resided for a time at Morgantown, Va., and for seven years at Uniontown, Fayette County, Pa. Here he delivered four orations commemorative of American independence, and a eulogy on General Washington. In 1801 he returned to Providence and engaged in private practice. In 1811 he was Professor of Materia Medica and Botany in Brown University. The Rhode Island Medical Society, in 1819, appointed him a delegate to the convention that formed the National Pharmacopœia. He possessed a fine classical education, and was a beautiful writer and an interesting lecturer. (b. March 11, 1753; d. Feb. 5, 1834.) Dr. Wm. Bowen studied medicine with his father, then a leading physician, and speedily acquired a large practice for himself. He avoided surgery, whenever practicable, and was deemed specially skilful in diseases of women and children. His instruction was much sought by pupils who were preparing to enter the medical profession. His reputation in the treatment of fevers was unequalled by any physician in his section. (d. 1832, æt. 86.) Dr. Caleb Fiske, a native of Rhode Island, served as a surgeon in the Revolutionary war, then settled in practice in Scituate, and passed a long and successful professional life, residing all the time in the house in which he had been born. He was one of the original members of the Rhode Island Medical Society, and in 1823 its president. At one time he was Judge of the Court of Common Pleas. He has perpetuated his name by endowing the Fiske fund for the promotion of medicine. (d. Sept. 1835, æt. 82.) To the names already mentioned I will add those of Drs. Levi Wheaton, Joseph Mauran, L. L. Miller, and David King—the first to introduce vaccination in Rhode Island.

South Carolina.[1]—Dr. James Moultrie, a native of South Carolina,

[1] South Carolina was one of the thirteen original States. The first settlement was at Port Royal by the English, in 1670. The government was a proprietary one till 1719, when South Carolina became a colony under the crown. During the Revolution the State was very active, and suffered much from the depredations of the British troops. The population in 1870, according to the U. S. Census, was 705,606, with about one in thirteen living in towns and cities of over five thousand inhabitants. The number of physicians was 798. There are two medical colleges, one at Charleston, and the other at Columbia. A State Medical Society was formed in 1789, and a State Medical Association in 1848; the latter publishes annually a volume of Transactions. Institutions for the care of unfortunates have been established.

The following medical journals have been published in South Carolina: Carolina Journal of Medicine, Surgery, and Agriculture, 1825; Charleston Medical Journal and Review, 1848; Charleston Medical Journal and Review, 1873; Southern Journal of Medicine and Pharmacy, 1846.

commenced practice in Charleston in 1813, and was soon afterwards appointed physician to the fort and jail. He took an active part in public health matters, and was soon recognized as the leading sanitarian of the city. In 1819 he was elected by the Medical Society of South Carolina a delegate to the first convention for forming the National Pharmacopœia. In 1822, he, with other influential medical men, memorialized the Legislature for a charter to establish a medical college, which was granted in 1823. He was elected to a chair in the college, but declined. In 1832, however, he accepted the chair of Physiology, and here developed the high powers of his well-stored and vigorous mind. He was President of the American Medical Association in 1851, and had previously been President of the Medical Society of South Carolina. (b. 1793; d. 1869.) Dr. Tucker Harris, a native of South Carolina, commenced practice in Charleston in 1771, in partnership with his preceptor Dr. Lionel Chalmers, and served as a hospital surgeon in the Revolution. Immediately after the restoration of peace, he resumed his practice. From 1783 to 1786 he had a business partnership with Dr. Oliphant. He was one of the earliest members, and an ardent friend, of the Medical Society of South Carolina, and from 1796 to 1799 was chosen its president. (b. 1747; d. July 6, 1821, æt. 74.) Dr. J. L. E. W. Shecut, a native of South Carolina, commenced practice in Charleston in 1791. He was attentive to business and a close student. In 1806 he exhibited an ingenious electrical machine of his own construction, and the same year published a work entitled "Flora Caroliniana." His publications were quite numerous. (b. 1770; d. 1836.) Dr. Alexander Baron, a native of Scotland, settled in practice in the city of Charleston in 1769. His fund of general information was great, and his ability equal to any position in professional or civil life. He was one of the founders of the South Carolina Medical Society, and its vice-president in 1790. In 1770 he joined the St. Andrew's Society, and was shortly after elected its president, an office which he held for twenty-eight years. (d. July 9, 1819.) Dr. J. Edwards Holbrook, a native of South Carolina, established himself in Charleston in 1822. In 1824 he was elected Professor of Anatomy in the Medical College of South Carolina. He was universally recognized as a learned scientist, and as a popular and successful physician. He avoided surgery, and was particularly noted for his sympathy for suffering patients. He was a successful medical teacher, and particularly popular with his class. Although contributing valuable articles to medical journals, his greatest works, and those on which his reputation as an author will rest, are his "American Herpetology" and "The Fishes of South Carolina." (b. Dec. 30, 1794; d. Sept. 8, 1871.)

Dr. John Bellinger, a native of South Carolina, commenced practice in Charleston, where his eminent abilities soon carried him, through all difficulties, to a full recognition of his professional abilities. His high reputation pointed him out as a proper occupant for the chair of Surgery in the Charleston Medical College, to which he was elected. His skill in surgery was only equalled by his acuteness as a physician. He was a thorough pathologist, and, although a busy practitioner, kept pace with the progress of the profession, and with the latest and best literature. (d. Aug. 13, 1860, æt. 56.)

Dr. Samuel H. Dickson, the physician, author, and teacher, commenced practice in Charleston in 1820. In 1823 he delivered a course of lectures on Physiology and Pathology before a medical class. He was influential in the establishment of the medical college at Charleston, and, in 1824,

was called to the chair of Institutes and Practice of Medicine. He was Professor of the Practice of Medicine in the University of New York from 1847 to 1850, when he returned to Charleston; but in 1858 was elected to the chair of Practice of Medicine in the Jefferson Medical College at Philadelphia, which he held nearly to the time of his death. He contributed many able papers to medical journals, and wrote a work entitled "Manual of Pathology," etc. (b. 1798; d. 1872.) Dr. B. B. Simons was a native of South Carolina. In 1801 he commenced practice in Charleston, and soon acquired business and reputation. His abilities were recognized by his appointment as Lecturer on Chemistry in the College of South Carolina. He was a thorough anatomist, and of rare skill and boldness in surgery, in which he acquired an extensive reputation and practice. (b. 1766; d. 1844.) Dr. Richard Evans Wylie, a native of Charleston, settled in 1832 in Lancaster Co., where he acquired distinction in his profession. He was a fine anatomist, and made many *post-mortem* examinations, and was a good pathologist. He was of a charitable and generous disposition, and was well versed in medical literature. (b. 1810; d. 1875.) Dr. Robert Wilson Gibbes was assistant and afterwards Professor of Chemistry, Geology, and Mineralogy in the South Carolina College, which position he filled with ability. He commenced practice in Columbia, where he acquired a good professional business. He was for several years sent as a delegate to the American Medical Association, and was President of the Medical Society of South Carolina. During the late war he was Surgeon-General of the State troops, and was the originator of the "wayside hospital system." Dr. Gibbes was an ardent student of the sciences, and the author of several valuable contributions to the Academy of Sciences and to the Smithsonian Institution. He was the author of Gibbes's History of South Carolina, and made a large collection of autographs, coins, and specimens in palæontology, geology, etc., as also a collection of the fossils of South Carolina. He was a member of the Royal Societies of England, France, Germany, and Denmark. (b. 1809; d. 1866.) I will add the names of Dr. David Ramsay, Dr. Geddings, and Dr. Peter Fayssoux.

TENNESSEE.[1]—Dr. Wm. H. Deadrick, a native of Virginia, having acquired his professional education, settled in East Tennessee. His operation for the removal of the inferior maxillary bone, in 1810, and other capital operations performed at that early date, have won for him an enduring name in the literature of the profession. (b. 1785; d. 1857.)

[1] Tennessee was the first State west of the Alleghany Mountains, settled by emigrants from the colonies, anterior to the Revolutionary war. The settlers were chiefly from North Carolina, to which State the territory belonged. Fort Loudon, in West Tennessee, was built as early as 1757. An attempt was made to found a State out of this territory under the name of "Franklin," but after three or four years' trial the effort was abandoned. Tennessee was admitted as a State in the Union in 1796. It has no very large cities. The population, according to the census in 1870, was 1,158,520, with about one in fifteen living in towns of over five thousand inhabitants. The number of physicians at that time was 2220. One medical college, organized in 1850 at Nashville, is well supported, and there is another, a department of Vanderbilt University. The profession of the State has a Medical Society, formed in 1830, which publishes Transactions annually. Institutions for the care of unfortunates have been organized in different parts of the State, sufficient for the wants of the people.

The following Medical Journals have been published in Tennessee: Memphis Journal of Medicine, 1853; Memphis Medical Journal of the Progressive Medical and Physical Sciences, 1851; Memphis Medical Recorder, 1852; Nashville Journal of Medicine and Surgery, 1851; Nashville Medical Recorder, 1860; Record of Medicine and Surgery, 1852; Southern Journal of Medical and Physical Sciences, 1853.

Dr. Felix Robertson, a native of Tennessee, wrote, for graduation in 1805, a thesis entitled "Chorea Sancti Viti," giving in it a history of the dancing mania which had exhibited itself in Tennessee, Kentucky, and Ohio about 1802. He was well read in his profession, and possessed strong common sense and original powers of observation. He was twice Mayor of the city of Nashville, and a member of the Board of Trustees of the University; and through a long life maintained the dignity and characte1 of an able physician. (b. 1781; d. 1865.) Dr. Wilson Yandell, a native of North Carolina, settled in 1804 in Hartsville, Rutherford Co. He was a man of mental vigor, untiring industry, and had a love for the acquisition of knowledge. His devotion to his profession rapidly advanced him to the front rank of practitioners in the State. He received from the University of Maryland the honorary degree of M.D. in 1823. He was the immediate ancestor of the physicians of the same name in Kentucky. (b. Dec. 17, 1774; d. Oct. 1, 1827.) Dr. A. H. Buchanan, a native of Virginia, commenced practice in East Tennessee, then removed to Columbia, and finally to Nashville where he became a professor in the Medical School on its organization. He was a man of learning and high character. (b. 1808; d. June 20, 1863.) Dr. John McClaran Watson, a native of North Carolina, settled in Murfreesboro, Tenn., but on the organization of the Medical Department of the University of Nashville, was induced to take the chair of Obstetrics and Diseases of Women and Children. He was a minister of the Gospel, as well as a successful practitioner, and a promoter of medical education. (b. 1796; d. 1866.) Dr. A. P. Merrill, a native of Massachusetts, served as a volunteer surgeon with General Jackson's Army in the War of 1812, and in 1819 was appointed surgeon in the U. S. Military service. In 1823 he resigned, and settled in practice at Natchez. In 1850 he removed to Memphis, Tenn., and assisted in organizing the Medical College at that place, taking the chair of Theory and Practice. He originated and edited the Memphis Medical Recorder. He was an able practitioner and an original writer, his contributions to medical literature being varied and valuable. (b. April 1793; d. Nov. 1873.) In addition to these I will name Drs. T. R. Jennings, James Roane, W. Walker, R. Porter, J. L. Armstrong, and Samuel Hogg.

TEXAS.[1]—Dr. Benjamin Briggs Goodrich, a native of Virginia, practised for some time after graduating in Alabama and Mississippi, finally locating in Washington, Texas. He was a member of the State Legislature, and on Texas resolving upon independence, was one of the signers of its declaration. (b. 1800; d. 1860.) Dr. Anson Jones, a native of Massachusetts, a patriot of Texas, commenced his career as a practitioner of medicine at Brazoria. He entered the Texan army as a surgeon, and was

[1] Texas until 1836 was a part of Mexico. In 1821, emigration to it from the United States became considerable. In 1830, it demanded admission to the Mexican confederation, as a separate State, but being refused, declared its independence, and conquered in a contest of arms, in 1836, maintaining its independence as a republic till it was admitted as one of the United States, in 1846. Its area is the largest of any of the States. There are no large cities in Texas; but it has a fertile soil, navigable rivers, and rich minerals. The population in 1870, according to the U. S. Census, was 818,899, with about one in twenty-five living in towns of over five thousand inhabitants. At the same time there were 1906 physicians. Population is increasing, and wealth accumulating. One medical college is located at Galveston, and is giving instruction. A State Medical Society was formed in 1869, and publishes Transactions annually. Institutions for the care of unfortunates have been established.

The following medical journals have been published in Texas: Galveston Medical Journal, 1866; Texas Medical Journal, 1873.

at the battle of San Jacinto. In 1837–8, he was a representative in the Texan Congress. In 1838, he was Minister to the United States, where he made an unsuccessful endeavor to secure the annexation of his country. On his return, he was made Senator from Brazoria to the Texan Congress. He was Secretary of State of Texas in 1841, and in September, 1844, was elected President of the Republic, and held this office up to the time of the annexation of Texas to the United States. (b. 1798; d. 1858.) Dr. Edward A. Pye, a native of Maryland, was a physician of eminence. He had a good practice at Hearne, in Robertson Co. When the yellow fever at Calvert had exhausted the medical men of that place, he offered his services, which were gladly accepted by the authorities. But this heroic act cost him his life. He contracted the disease, and died. During the war, he served as surgeon at Beaumont. (b. July 9, 1818; d. Nov. 9, 1873.) Dr. John A. Pettus, a native of Virginia, settled at Fort Bend, Texas, where he acquired a large practice. During the late war, he was Medical Director of the Corps of Surgeons of U. S. Volunteers. After the war, he returned to practice, and was elected Professor of Physiology and Medical Jurisprudence in the Galveston Medical College. (d. Sept. 26, 1870, aged 52.) Dr. E. L. Massie was a skilful and benevolent physician of Houston. During the war, he served as a surgeon in the Confederate army, and was afterwards Medical Purveyor of Texas. He was one of the leading physicians of Houston. I will name in addition, Drs. E. T. Bonney, Alva Connell, W. Riddell, George W. Peete, W. D. Robinson, Wm. Richardson, W. R. Smith, and Wm. McCraven.

Vermont.[1]—Dr. Joseph Adams Gallup, a native of Connecticut, settled in practice at Woodstock, Vermont, in 1800. He possessed a vigorons mind, and was a close observer and correct reasoner. By skill in his profession, and by force of character, he acquired a leading business. He was Professor in the Castleton Medical College, and in the Medical College of the University of Vermont. In 1827 he founded the medical school of Woodstock. His best known writings are entitled "Sketches on Epidemic Diseases in Vermont," published in 1815, and "Outlines of Institutes of Medicine," published subsequently. (b. Mar. 30, 1769; d. Oct. 12, 1849.) Dr. Noadiah Swift, a native of New York, commenced practice in Burlington about 1802, and enjoyed a large practice for nearly fifty years. He was a man of great energy of character, and of correct habits, and possessed rare skill in his profession. His reputation extended far beyond the community in which he resided. He was elected at different times to the State Senate. (b. Nov. 24, 1776; d. Mar. 21, 1860.) Dr. Benjamin R. Palmer commenced practice in Woodstock, Vermont, where he acquired much popularity, and a good professional business. He possessed decided talents as a teacher of anatomy and physiology. He was elected to the chair of Anatomy in the Vermont Medical College, where he taught for many years with success. He also held the same

[1] Vermont was settled by emigrants from Massachusetts, New Hampshire, and New York, each of which States claimed her territory. In 1791 Vermont was admitted as the first new member of the Union. The population in 1870, according to the United States Census, was 330,531. She has no large cities, and about one in twenty-three of her population live in towns of over five thousand inhabitants. She had at the time mentioned 569 physicians. Vermont has one medical college, a department of the University of Burlington. A State Medical Society was organized in 1814, and publishes Transactions annually. A registration of vital statistics has also been established. Institutions for the care of unfortunates have been founded, sufficient for the wants of the people.

The following Medical Journal has been published in Vermont: Vermont Medical Journal, 1874.

chair in the Berkshire Medical College of Massachusetts. His reputation as a teacher gained him the election to the chair of Anatomy in the Louisville Medical College, when he removed to Kentucky, where he enjoyed an extensive practice up to the time of his death. Dr. Benjamin Chandler, a native of Connecticut, commenced practice in 1792 in Rutland, Vermont, where he acquired reputation, and whence he removed to St. Albans in 1807. As a successful operator in surgery, he had no equal in that section of the country. He was one of the founders of the Vermont State Medical Society, and of the Franklin County Medical Society. (b. 1772; d. 1818.) Dr. John Pomeroy, a native of Massachusetts, was a physician of ability. He settled in Cambridge, Vermont, in 1787, and in 1792 removed to Burlington, where he remained actively engaged in practice for over forty years. He was a man of vigorous intellect, and was characterized by simplicity of manner, directness of purpose, and strong common sense. Although he could not claim superior education, he was an ardent supporter of it. He was a member of the Corporation of the University of Vermont, and a professor in the Medical Department. (b. April 9, 1764; d. Feb. 19, 1844.) Dr. Jonathan Adams Allen, a native of Massachusetts, commenced practice at Windham, in 1814. In 1820 he commenced to give lectures on Chemistry, at Middlebury College, and continued till 1826. In 1822 he removed to Middlebury, where he became extensively engaged as a physician. He was an active member of the State and County Medical Societies. (b. Nov. 17, 1787; d. Feb. 2, 1848.) Dr. Horace Eaton, a native of Vermont, commenced practice in Enosburgh about 1824, and soon became popular as a physician. He was a man of great energy, and fully qualified in the duties of physician and surgeon. He was elected to the Legislature of the State, and was six years in the State Senate. He was also Lieutenant Governor and Governor of the State for two years. He was greatly interested in education, and was for years State Superintendent of Schools. In 1848 he was elected Professor of Natural History and Chemistry in Middlebury College, a position which he filled with credit to himself and the Institution till the time of his death. (b. June 22, 1804; d. July 4, 1855.) To these names may be added those of Dr. Theodore Woodward, of Castleton; Dr. David Palmer, of Woodstock; Dr. Ezekiel Porter, of Rutland; the Drs. Tudor, of Middlebury, and Dr. Danforth.

VIRGINIA.[1]—Dr. Wm. Baynham, a native of Virginia, studied medicine with his father, and then with the celebrated Hunters of London. He was an excellent anatomist, and was held in high esteem by his London preceptors, and by Mr. Cline and Mr. Else. He made some deli-

[1] Virginia was, in 1607, the seat of the first permanent settlement by the English in America, at Jamestown. Her first charter was annulled in 1677, and a new one, less liberal, granted. She took an early and decided stand in favor of American Independence. Her territory at that time was very large, and in 1781 she ceded the whole northwestern part to the U. S. government. In 1861 the western part of the State was formed into a separate State, under the name of West Virginia. Her geographical position gives her great commercial advantages. The population of Virginia, according to the U. S. Census in 1870, was 1,225,163, about one in ten living in cities of over five thousand inhabitants. The number of physicians was 2226. There are two medical colleges, one at Richmond and the other at the University, at Charlottesville. The State Medical Society, formed in 1821, publishes Transactions annually. Institutions sufficient for the care of unfortunates have been organized in different parts of the State. The first Insane Asylum in this country, under State authority, was established at Williamsburg in 1773.

The following medical journals have been published in Virginia: Monthly Stethoscope and Medical Reporter, 1856; Richmond Medical Journal, 1866; Virginia Clinical Record, 1871; Virginia Medical Monthly, 1874; Virginia Medical and Surgical Journal, 1856.

cate dissections and minute injections, which are still on the list of preparations at St. Thomas's Hospital. He practised for some years in London, but returned to Virginia, and settled in Essex Co. He was, without question, the most celebrated anatomist and surgeon in his day in America. Although being in a sparsely settled region, he was consulted by many persons from a distance, and frequently made long visits to perform surgical operations. (b. Dec. 7, 1749; d. Dec. 8, 1814.) Dr. James McClurg, a native of Virginia, served during the Revolutionary war as a surgeon, and part of the time as Medical Director. He commenced practice at Williamsburg in 1773, and soon won his way to recognition as a physician of high culture and skill. He had published in London, in 1772, a thesis on the Bile, which attracted the attention of the profession. On the removal of the State government from Williamsburg to Richmond in 1793, the doctor took up his residence in the latter city. By virtue of his decided skill, he was for nearly fifty years at the head of the profession of Virginia. (b. 1746; d. July, 1823.) Dr. Wm. B. Selden, a native of Virginia, settled in practice in Norfolk in 1799, and was fully employed for half a century. He was an elegant scholar, retaining his love for the classics to the close of his life. He was a careful reader of the best medical literature, and a close observer of disease. In 1799 he obtained from Dr. Jenner some vaccine virus, with which he continued to vaccinate, and with which he kept up a continuous supply for fifty years. He declared that he could see no variation in the appearance of the vesicle, nor any failure in its power of protection in all this time. (b. Aug. 31, 1773; d. 1849.) Dr. Beverly R. Welford, a native of Virginia, settled in practice in Fredericksburg in 1816, when he was scarce twenty-one years of age, and soon won the confidence and affection of a large circle of friends and patients. He was a man of liberal studies, and enthusiastically devoted to the advancement of the medical profession. In 1854 he was elected to the chair of Materia Medica and Therapeutics in the College of Virginia, and removed to Richmond. His courteous manners, ripe experience, and professional knowledge soon made him the popular physician of that city. In 1852 he was President of the American Medical Association. (b. July 29, 1797; d. Dec. 20, 1870.)

Dr. Hugh Holmes McGuire, a native of Virginia, commenced his career as a medical man in Winchester, Va., and soon developed a preference for surgery. His first operation was for cataract, which he successfully performed with a needle made under his direction by a mechanic in Winchester. In 1827, with other physicians, he established the Winchester Medical School, in which he was Professor of Anatomy and Surgery. In 1847 this instituton obtained a charter, and continued in successful operation till the beginning of the war. In 1862 the buildings were burned by soldiers under Gen. Banks. In the same year the Doctor was commissioned as surgeon in the Confederate Army, and served till the close of the war. He was tendered a professorship in a medical school at Philadelphia, and also at New Orleans. In 1850, he was elected one of the Vice-Presidents of the American Medical Association. He was a man of great industry, and had wonderful success as a surgeon. He performed lithotomy thirty times without losing a case. (b. 1801; d. 1875.) Dr. James Craik, a native of Scotland, was a surgeon in Braddock's expedition against Fort Duquesne, and also a surgeon in the Revolutionary Army. After peace was established, he settled in practice near Mt. Vernon, in Virginia. He was a warm personal friend of Gen. Wash-

ington, who mentioned him in his will, as his "old and intimate friend." The Doctor was one of the three physicians who attended Gen. Washington in his last illness. He was a thoroughly educated physician and surgeon, and a man of great probity of character. (b. 1731; d. Feb. 6, 1814.) Dr. George Cabell, a native of Virginia, practised for years with success and reputation at Lynchburg. He was a man of superior endowments and much culture. His practice extended for many miles along the valley of the James River. (d. 1823.)

Dr. J. P. Mettauer, a native of Virginia, practised in Prince Edward County. He was in many respects one of the boldest and most successful surgeons in the State. He commenced practice in this sparsely settled region about 1809, and during a long life maintained the character of a learned and skilful physician and surgeon. No medical man in the South was better known for his success, and for his valuable and numerous contributions to medical literature. Even when past eighty years of age, he was active and energetic in practice, and performed important surgical operations with success. (d. Nov. 22, 1875, aged 88.) Dr. Francis T. Stribling settled in Staunton, Va., where he soon acquired a large practice by devotion to professional duties. In 1836 he was elected physician to the Western Lunatic Asylum, and in 1840 was appointed Superintendent, which position he filled with great success to the time of his death. He possessed a strong intellect, and introduced many improvements in the management of the insane. (b. Jan. 20, 1810; d. July 23, 1874.) In addition I will mention Drs. Charles B. Gibson, James Henderson, John Minson Galt, Thomas Massey, Goodridge Wilson, Thomas Robinson, P. C. Spencer, Micajah Clark, James Bolton, John Cullen, James Currie, R. W. Haxall, B. H. May, A. L. Warner, H. Selden, G. N. Upsher, J. B. Strachan, J. S. Giliaim, J. B. McCaw, A. G. Strachan, John Field, John F. Peebles, T. R. Atkinson, D. J. Claiborn, R. B. Butt, besides the forty-five martyrs who died of yellow fever at Norfolk in 1855.[1]

[1] I believe that a complete record of the names of the physicians who died during the great epidemic of yellow fever in Norfolk, in 1855, has not found a place in medical literature. The list given here is taken from the Virginia Medical and Surgical Journal for Oct. 1855, p. 338, from the Portsmouth Relief Association's report, from Forrest's "Great Pestilence in Virginia," and from other sources. It will be observed that in some cases no first names are given. In the midst of the terrible panic and distress that existed, these noble men were buried without any special ceremony, but were conveyed silently to their graves. We honor their courage and devotion to professional duty, which was equal to that which, in the church, purchased the title of Saint. Over one hundred physicians volunteered their services, and actually went to Norfolk and Portsmouth during the epidemic. Forty-five medical men are known to have died of yellow fever in these cities, and, so malignant was the disease at one time, that seven physicians died upon one day, and five on another. A majority of the deaths of physicians took place among those who came from other places to render assistance to their medical brethren and the citizens in their great distress. While it is probable that I have not obtained the names of all, it is possible that some in the list may have been druggists and not graduates in medicine. The following are the names in alphabetical order, with the place of residence when known:—

Bache, Berry, J. L. (Memphis, Tenn.), Berry, R. B. (Tenn.), Blow, Richard (Sussex, Va.), Booth, T. (Baltimore, Md.), Briggs, J. A. (Norfolk, Va.), Burns, Capri (a Hungarian), Cole, C. (Philada., Pa.), Collins, Wm., Constable, T. F. (Norfolk, Va.), Craycroft, T. H. (Philada., Pa.), Crowe, N. J. (Richmond, Va.), Dabershe (Dist. of Columbia), De Berane, Dillard (Montgomery, Ala.), Fliess (Baltimore, Md.), Gilbardt, Leon (Richmond, Va.), Gooch, P. C. (Richmond, Va.), Halson, G. I. (Norfolk, Va.), Handy, T. W. (Philada., Pa.), Higgins, F. L. (Norfolk, Va.), Howe (Baltimore, Md.), Howle, Thos. P. (Richmond, Va.), Hunter, Edwin (Brooklyn, N. Y.), Jackson (Dist. of Col.), Lovett, M. P. (Portsmouth, Va.), Marshall (Baltimore, Md.), Mierson, T. (Philada., Pa.), Morse, Nash, Thos. (Norfolk, Va.), Nicholson, L. P. (Portsmouth, Va.), Obermuller (Georgia), Parker, R. H. (Portsmouth, Va.), Rizer (Penn.), Schell (N. Y.), Selden, Henry (Norfolk, Va.), Sil-

West Virginia.[1]—Dr. James W. Clemens, a native of Pennsylvania, commenced practice in Wheeling in 1819. He was not only solicitous for business, but ambitious for knowledge, and a constant reader of the best medical literature. He had a private chemical and pathological laboratory attached to his office, in which he was constantly experimenting. He was a ready writer and a fluent speaker, and enjoyed through life the reputation of a successful physician. (b. May 26, 1795; d. Nov. 21, 1841.) Dr. Martin L. Todd, a native of New York, commenced practice in Wheeling in 1810, and soon acquired reputation in the treatment of a then prevalent low grade of fever, popularly called the "Cold Plague." He served as a surgeon with the State troops in the war of 1812. He was remarkable for his acuteness in diagnosis, as well as for his choice of efficient remedies. (b. 1782; d. March 8, 1866.) Dr. S. P. Hullihen, a native of Pennsylvania, commenced practice as a surgeon and dentist in 1832, and the same year received the degree of Doctor of Medicine from Washington Medical College, Baltimore. He was a man of genius, gifted with original conceptions, and with ability to overcome difficulties in surgical operations, and to make efficient appliances. He never was a general practitioner. To him belongs the credit of originating the movement for the establishment of the Wheeling Hospital. He contributed some valuable articles to Medical Journals, the result of observation and experience. His death was regretted by all classes, and at a public meeting a spontaneous subscription was made to erect a monument to his memory. (b. Dec. 10, 1810; d. March 27, 1857.) Dr. R. H. Cummings, a native of Pennsylvania, commenced practice in Wheeling. His professional qualifications were of the first order. He was a ready writer, and a close observer of all the conditions that affect health. He occasionally contributed to medical literature, and was President of the State Medical Society in 1872. (b. Feb. 17, 1817; d. April 12, 1873.) In addition to the foregoing, I will name Drs. Samuel McKeehan, John W. Moss, H. D. Chapman, and James Tanner.

Wisconsin.[2]—Dr. Mason C. Darling, a native of Massachusetts, settled in 1830 in Fond-du-Lac, Wisconsin, the pioneer physician of that place. He had formerly practised for about thirteen years in Greenwich, Mass., where he had acquired experience and reputation. In addition to being a good physician, he was an energetic far-seeing business man. These qualities caused him to be put forward in politics, and he was elected to

vester, Richard J., and Silvester, R. W. (Norfolk, Va.), Smith, J. C. (Columbia, Pa.), Thompson, Robt. (Baltimore, Md.), Trugien, J. W. H. (Portsmouth, Va.), Tunstall, R. B. (Norfolk, Va.), Upsher, G. L. (Norfolk, Va.). Walters, Charles (Baltimore, Md.).

[1] West Virginia formed a part of Virginia until 1861, when a convention at Wheeling formed it into a new State; and it was admitted into the Union Dec. 31, 1862. The population in 1870, according to the U. S. Census, was 442,014, about one in twenty living in cities and towns of over five thousand inhabitants. The number of physicians was 612. A State Medical Society, organized in 1867, prints annually a volume of Transactions. Institutions for the care of the insane and other unfortunates have been established.

The following medical journal is published in West Virginia: West Virginia Medical Student, 1875.

[2] Wisconsin was early visited by the French missionaries, and permanent settlements were made in the latter part of the 17th century. It was erected into a territory in 1836, and admitted as a State in the Union in 1848. Population and wealth are rapidly moving to it. The U. S. Census of 1870, assigns to it a population of 1,064,985, with about one in eight living in towns of over five thousand inhabitants. The same authority gives 915 physicians. The agricultural resources are of the first order. A State Medical Society and a State Board of Health have been organized; the first, formed in 1842, has for years published Transactions.

the Legislature and also to the State Senate, where he took a prominent part in favor of educational projects. He was one of the originators and first President of the State Historical Society. (b. May 18, 1801; d. March 12, 1856.) Dr. John B. Donsman, a native of Michigan, commenced practice in 1826 with his preceptor Dr. Twitchell, of New Hampshire. In 1840 he came to Wisconsin, and settled in Milwaukee, where he practised with success up to the time of his death. He was a man of clear perceptions, great stability of character, and devotion to his profession. He was a member of the State Medical Society and of the American Medical Association. (b. 1807; d. 1868.) Dr. Clark G. Pease, a native of New Hampshire, commenced practice in Holyoke, Mass., in 1849, but in 1850 removed to Janesville, Wisconsin. His agreeable address and skill as a physician soon won him a numerous class of patrons. He was an influential member of, and one of the best workers in, the State Medical Association, acted on nearly every committee of importance, and was elected President in 1857. He contributed papers to the State Society, and also to the American Medical Association. He served as a surgeon in the late war, and lost his life from a dissection wound. (b. Dec. 31, 1821; d. June 27, 1864.) Dr. Alexander McDill, a native of Pennsylvania, after practising for fifteen years in his native State, removed in 1856 to Wisconsin, and settled in Plover, Portage Co., where he became fully employed. In 1862–3 he was sent to the Legislature, and the following year to the Senate. In 1868 he was chosen Superintendent of the State Hospital for the Insane. In 1872 he was elected to Congress, but at the expiration of his term of office, resumed his place as Superintendent of the Asylum. (d. Nov. 12, 1875.) In addition to the foregoing, I will name Drs. Henry M. Lilly, Moses Barrett, H. O. Crone, A. Blanchard, B. F. White, and Corydon Farr.

My task here ends. A century of American Medical Biography has been traversed. Of necessity, the memoirs are very brief. The claims of every part of our country have however been considered. The retrospect is finished: I would it were worthier of the occasion. And in conclusion I wish to bear testimony to the fact that the study of the lives of the physicians of America, for the Centennial period, has produced in me, as I trust it will in others, a profound conviction that eminence and honorable distinction in the profession, are the legitimate results of good education and professional knowledge, conjoined with high moral character and devotion to duty. These qualities, with a desire to do good and an active sympathy for our race, stand out so prominently in the lives of all truly eminent physicians, as to appear to be essential traits of professional character. So uniformly are love of man and devotion to duty characteristic of the true physician, that it is not arrogant to claim for him a higher approbation, as in the vision of Abou Ben Adhem, who saw that the name of him who loved his fellow men "led all the rest," on the roll "of those whom love of God had blest."

When in the course of time another century of American Independence shall have been concluded, the professional men then occupying our places may perchance choose to meet as we have done, and, casting a retrospective glance across the second century, contrast their position and the progress then attained with that which marks our era. And while I trust that they may have abundant reason to congratulate themselves upon the advance which medicine shall have made, I doubt not they will have an honest pride in the monuments, legacies, and records left by

the profession during the century just closed. These have in part been referred to in the addresses and papers read before this Congress. Permit me to indulge the hope that the biographer of the next Centennial may have as great pleasure and satisfaction in the study of the lives of the medical men of the second century of our country, as I have enjoyed in the preparation of this address. I am persuaded that the temple of fame holds no more honored tablets than those on which are inscribed the names and deeds of the worthy members of the Medical Profession. That the members of this Congress may deserve to have their names perpetuated to fame through all succeeding ages, is my earnest prayer. To have my own there enrolled, I may not hope, since this is granted to but the immortal few.

ADDRESS ON OBSTETRICS.

BY

THEOPHILUS PARVIN, M.D.,

PROFESSOR OF OBSTETRICS AND THE MEDICAL AND SURGICAL DISEASES OF WOMEN, COLLEGE OF PHYSICIANS AND SURGEONS OF INDIANA.

"There is no department of medicine or surgery, superior to midwifery in dignity and utility."—*Mauriceau.*

Of American Obstetrics, with its associate branches, Gynæcology and Pædiatrics, we commemorate the centennial.

What have Americans done, in the century just closed, to advance these great departments of Medicine? How easy the question and how difficult the answer! Contemporaneous discoveries and successes are found in these as well as in other fields of human effort, and who, then, shall be *primus inter pares!* Sometimes, too, that which is supposed to be new[1] is really old, and the discoverer has unconsciously trodden in the footsteps of another.

Beside this, much of medical knowledge is merely provisional, the best expression of the truth for the time being, and serves only a present utility—a mere ladder by which we ascend to higher platforms and larger planes, and which is then cast aside. Nor does everything claimed as valuable by him who first points it out, prove to be such when thoroughly tested. Alas, for the many Ixions who mistake a cloud for a goddess! Alas, for the fool's gold that so often delights, so surely disappoints! Change is not synonymous with improvement; so far from change always being progress, it may be retrogression.[2]

Nor are these the only difficulties. Add to them the limitation of individual knowledge, and the infirmities of human judgment, so liable to error in estimating the value of things present, no matter how determined and desirous one may be *suum cuique tribuere.* And surmounting all these, there stands in bold relief the fact that the very work of this occasion has been largely anticipated by an able paper in the American Journal of the Medical Sciences,[3] from the pen of one who has himself contributed so much to the glory of American Medicine. Confronted by such difficulties, and addressing such auditors, one even of ample qualifications might well shrink from attempting the duty assigned me.

However, strengthened by your recognition of these impediments, and

[1] Professor Blackie, *Horæ Hellenicæ*, observes: "Even in the free exercise of poetical talent in the case of individual poets of highly potentiated imagination, we constantly stumble on comparisons which have been made independently by other poets at other times or in distant countries, and which superficial critics are sometimes eager to fasten on as plagiarism." Quite similar facts are observed in the history of medicine.

[2] Baudelocque, Vol. II, pp. 34, of *L'Art des Accouchemens*, Paris, 1781, in referring to the obstetrical forceps remarks: ". . *car si plusieurs ont travaillé à sa perfection, les autres ne l'on rendu que plus imparfait.*"

[3] July, 1876. A Century of American Medicine. III—Obstetrics and Gynæcology. By T. Gaillard Thomas, M.D.

confiding in your earnest sympathies with this work, I address myself to it with zealous desire to honor justly both the dead and the living of our country, who have added useful knowledge in obstetrics, and in diseases of women or of children, and to help exalt their fame in all they have thus done to lift or lighten the cross of human suffering.

In this proposed exposition, the subject of Obstetrics will, for obvious reasons, be presented first. After some brief allusions to the condition of obstetric art and science in the last century, and the sources from which the first American practitioners of this art derived their knowledge, suitable topics will be found in works on Obstetrics, and in special contributions to obstetric pathology and therapeutics.

The eighteenth century was marked by great advances in obstetric knowledge and improvements in practice, though history has shown the mistake of a distinguished physician of South Carolina, Dr. David Ramsey, who, in an address before the Medical Society of his State, on the first day of the present century, asserted "that the art of obstetrics had been brought to such perfection, further improvements were scarcely to be expected."

Standing at the commencement of the eighteenth century is the famous Hollander, Deventer, who declared theory as essential to practice as body to shadow—surely a very doubtful compliment to practice—who asserted that those[1] ignorant of the obliquities of the uterus were equally blind with him that saw trees as men walking, but who, despite these and similar exaggerations, despite plain, palpable errors, advocated cephalic version, and taught the genu-pectoral position as part of the treatment in one variety of prolapse[2] of the cord, and in some cases of transverse[3] presentation.

Near its close we have the illustrious Baudelocque, to whom so many of our obstetric authors acknowledge their obligations, and whose fame, notwithstanding his twenty-three presentations and ninety-four positions, has suffered only partial eclipse in the revolutions of more than four-score years. And interposed we have Chapman coming from the country to London once a year to give lectures on obstetrics, the first,[4] and the first ever given in that city, being in 1730, and revealing the beneficent instrument which the Chamberlens had kept secret with cruel cupidity, the obstetric forceps; we have Sir Fielding Oulde, the wit's "Lord deliver

[1] . . quicunque obliqui situs uteri sunt ignari, in artibus obstetricantium æque cecutiant, ac ille, qui homines instar arborum videbat ambulantes. Henrici à Deventer, Medicinæ Doctoris, Operationes Chirurgicæ Novum Lumen exhibentes Obstetricantibus, etc., Leyden, 1701.

[2] Similiter accidit sed rarius, ut *funiculus* à capite retrorsum *vertebris* vel *ossi sacro* apprimatur: tunc caput alterutra manu removendum, prout scilicet plus minus in alterutrum latus vergit; parturienti (si vires suppetant) in *genua provolutæ* à tergo manum sospitam admoveat *obstetrix:* aut, si infirmior fuerit, in *alterutrum latus* declinetur, *uno pede ad ventrem attracto*, ut plus spatii suppetat, etc., Ibid., cap. xxxviii. De partu difficili, ab infante prævia vena umbilicali prodeunte.

[3] . . . ideoque parturientem, tali situ disponat, quo uteri spatium suppetat, nec ille cum infante in manum *obstetricis* delabatur; nimirum *utero propendulo* convenit parturientem *procumbere genibus*, aut *in dextrum latus inclinare*, posteriore corpore aliquatenus elevato, et ut plurimum prono, etc., Ibid., cap. xl. De infantibus transversim positis.

[4] My authority is Dr. Thyme. Vide MSS. Lectures, 1794, Surgeon-General's Library, Washington. Dr. T. remarks, "Chapman had no machines, nor were his students allowed to attend midwifery cases. To Smellie we owe those improvements." Denman, however, credits Dr. Maubray, 1724, with the first lectures.

us," giving a glimpse at the mechanism of labor, that mechanism soon to be much more fully and clearly expounded by Smellie and Solayres; we have Smellie and William Hunter, representing opposite but concordant elements of obstetrics, mechanism and physiology, the one writing a work upon obstetrics, the fruit of forty years' study, which for nearly three-quarters of a century was the best English text-book, and enduring the harmless criticism of Dr. Burton, who probably had his reward in being made the Dr. Slop of Tristram Shandy; the other preparing those plates of the human gravid uterus, which can never become obsolete; we have Levret, the geometric obstetrician, explaining the mechanism of labor before the Paris Academy of Surgery, using in his demonstrations the egg of an ostrich and a "mattrice mechanique," and dividing with Smellie[1] the honor of an important improvement in the forceps. With these two men, using the words of Baudelocque, commenced the most brilliant epoch of obstetric art.

But it is not my purpose to mention further the famous obstetricians of the eighteenth century, and allude to any of their special contributions. Enough to add that the two first American obstetric practitioners had been instructed by two of the most eminent of London teachers, for Lloyd,[2] in Boston, and Shippen,[3] in Philadelphia, were pupils of Smellie and Wm. Hunter. Thus we see that the germ of American Obstetrics was British rather than French, in so far giving probable contradiction to the assertion of Dr. Tyler Smith when he states, "notwithstanding the blood relation between the United States and this country, American Midwifery is far more the child of France than of England." So, too, probable contradiction is given by these other facts, that Dr. Samuel Bard, the author of the first American work on obstetrics, had received his professional training largely in Edinburgh; and that there, too, after having previously been a house-pupil in London under Drs. Osborne and John Clarke, was instructed Dr. T. C. James, the first professor of obstetrics in the University of Pennsylvania. And the famous Dewees, who bears the same paternal relation to American Obstetrics that Physick does to American Surgery, or Rush to American Practice, and who "has the high honor of first attempting a full course of lectures on obstetrics in America,"[4] was too independent a thinker and original investigator to be unduly swayed by the teachings of any man or of any school.[5] And finally, the obstetric books of the American profession have been British or American much more than French.

Seventy or eighty years ago, the practice of obstetrics was almost exclusively in the hands of women, even in the long settled parts of the United States, and, as the tide of population passed westward, the female midwife was still the trust of the matrons among the early settlers who

[1] Possibly, according to the recent researches of Dr. McClintock, each of them was anticipated by Dr. Pugh (see Dublin Journal, June, 1876), so that there is an end to the contest in this matter between France and England.

[2] Dr. Bartlett, of Massachusetts, states that Dr. James Lloyd, of Boston, was the first systematic practitioner of midwifery in that section of the country, 1754.

[3] In 1756 Dr. William Shippen engaged in the same practice at Philadelphia, and subsequently was Professor of Anatomy, Surgery, and Midwifery in the University of Pennsylvania.

[4] Eulogium upon William P. Dewees, by Prof. Hugh L. Hodge. These lectures were first delivered in 1797.

[5] "Drs. James and Dewees should be regarded as the fathers of obstetric science in America: the former, erudite and polished, gave currency to the teachings of the British schools; the latter, more vigorous and energetic, exemplifying theoretically and practically the doctrines of the French obstetricians."—Preface to Hodge's Obstetrics.

swept away the forests and founded an empire beyond the Alleghanies. Dr. J. G. F. Holston[1] has given a most graphic description of early midwifery in Ohio; but the compensation of these practitioners, as stated by him, seems so meagre that none could have had a lucrative practice, no matter how large it was—one dollar, and in cities not more than three dollars, and in the country the midwife was also nurse the first week or until the ninth day.

Nor had the American midwife any of the posthumous honors which were once the fortune of her sisters in France. That famous *sage-femme*, Louise Bourgeois—whose picture[2] Dr. Goodell has with such perfect art recently exhibited to the profession—in her Instructions to her daughter, Paris, 1617, states, "There are now very few women who have such an affectionate regard for their midwives as prevailed formerly, when it was the custom, if a midwife died, for her friends to put on deep mourning for her, and they prayed God not to send them any more children,"[3] etc.

However the fact remains that the general practice of obstetrics in this country has been but for little more than half a century chiefly devolved upon medical men, and even to this day, in most of our large cities, a considerable portion of this practice, more especially among the foreign population, is attended to by females.

The first American work on obstetrics was the Compendium of Midwifery, by Dr. Samuel Bard, of New York, the first edition being issued in 1808, the fourth and last in 1817. Using the phrase of the present day, this book is remarkable for its amount of *padding*, page after page being filled with extracts from Smellie, Perfect, Clarke, and various writers in the Medical and Physical Journal. But it also contains many judicious thoughts and directions well expressed by Dr. Bard, and from the very number and variety of important cases quoted, is really an excellent compend of clinical obstetrics. In meeting that *nodus obstetricus*—why labor occurs at nine months, Dr. Bard does not shelter himself with Avicenna behind the grace of God, but assails the question with a brace of questions, Why do strawberries ripen in June and peaches in August?

In reference to the delivery of the placenta, he certainly was greatly in advance of many obstetric authors of recent days, advising almost essentially Crêdé's method before Crêdé was born, as the following passage clearly shows. "While this is about," *i. e.* attention to the new-born child, "let an assistant or the woman herself, place her hand on the abdomen, a little above the fundus uteri, so as in some measure to grasp it in the palm, and make a moderate pressure upon it. This can possibly do no harm; it has been my general practice; and I think I have found a manifest advantage from it in promoting the contraction of the uterus and in disengaging the placenta."

And in the management of women after parturition the following instructions seem wise, though even at this day they are too generally neglected. "After one or two days, women should rise from their beds, and sit up for a longer or shorter time every day, according to their

strength and inclination." "The lochia require no other attention than sitting up a short time every day to promote their evacuation."

Of wider scope, of more originality, and destined to a much larger fame, was the Compendious System of Midwifery, by Dr. Dewees, first issued in 1826, of which no less than twelve[1] editions have been published. Dewees himself had some years before, 1807, published an abridgment of Heath's translation of Baudelocque, with annotations, and it passed through at least three editions. Burns's Principles of Midwifery was republished in 1810, with notes by Dr. Chapman, and several subsequent editions edited by Dr. James; in 1821, Denman's Introduction to the Practice of Midwifery, with very valuable notes by Dr. John W. Francis, was issued in New York. But not Baudelocque, nor Burns, nor Denman was to be the first great obstetric teacher of the American profession. He who was to have this honor was no favored child of fortune, but one early in youth left fatherless and poor, with no heritage but a good name, with few facilities for acquiring a complete literary education amid the desolations of the Revolution, yet bravely struggling up against rude adversities. His first professional labors were those of a country practitioner in one of the pleasantest[2] of villages—once hidden away, surrounded by farms or forests—now almost lying within reach of the outstretched arms of this great city. There he acquired those habits of close observation and reflection which were the foundation of his future greatness and fame. Then, after four years' experience casting his lot in Philadelphia, and without fortune, without family influence, without professional friends save as they were attracted to him by the recognition of his abilities—no adventitious aids—he succeeded by his own inherent power and perseverance. The name of William Potts Dewees should live forever in the memory of the American profession.

Dr. Hodge, in speaking of Dr. Dewees in 1842, observed: "He is our representative to other nations on the science of obstetrics, and as such is continually quoted by European authorities, as if he constituted one of their own number.[3]" As to the merits of Dewees's Midwifery, let me again quote the opinions of Dr. Hodge. He considered it, twenty years after its publication, as "probably the best practical book in our profession." "It takes a stand decidedly in advance of Denman, Osborne, Burns, and other English authorities in general use in our country at that period, and even of Baudelocque himself," etc. Without acceding to the truth of Pope's couplet—

> "Authors, like coins, grow dear as they grow old;
> It is the rust we value, not the gold,"

[1] "An honor rarely, if ever, bestowed on any similar work."—History of American Medical Literature. By Professor S. D. Gross.

[2] Abington, Penna.

[3] "Dr. John Ramsbotham, of London, dedicated the second part of his 'Practical Observations on Midwifery' to Dr. Dewees, in connection with Sir C. Mansfield Clark. Dr. Edward Rigby, of London, and author of a most excellent work on Obstetrics, which has lately been republished in this country, writes to Dr. Dewees in August, 1834, in the following manner:—'I trust you will pardon the liberty I have taken in writing to you, as well as the motives which have induced me to do so. I have been accustomed, for some years, to hold such frequent intercourse with you in reading your admirable system of Midwifery, and work on children, that I cannot refrain from requesting a more direct intercourse between us,' etc. The July number of the British and Foreign Medical Review, for 1839, contains the following handsome compliment:—'The Philadelphia school of Midwifery has for many years been looked upon with great respect by the obstetricians on this side of the Atlantic. The high name and professional standing of Dr. Dewees, his great experience, and, above all, his inestimable, compendious system of Midwifery and other valuable publications, have mainly contributed to this result.'"

let me predict that as with pious care and grateful appreciation one of the most celebrated of the Dublin school is bringing the "Treatise" of Smellie before this generation, so this or a succeeding generation will see the avatar of the "Compendium" of Dewees in like modern form.

To Dr. Dewees, probably, we are more indebted than to any one else, for the general preference on the part of the American profession for the long forceps.[1] Dr. Dewees[2] accomplished great good in exposing the errors of Denman in his aphorisms as to the use of this instrument, and the practice of the former is much more in accordance with that of to-day, than is that of the latter: an apparent timidity and conservatism ruled Denman's teachings in this regard, which conduced to the interests of neither mother nor child—he was a representative of that *physiological* school of obstetrics, originating with William Hunter, in opposition to what Tyler Smith has termed the *mechanical* school of Smellie—but our American obstetrician represented both in harmonious union.

To Dr. Dewees belongs the honor of pointing out the value of venesection not only in overcoming rigidity of the os uteri, but also in diminishing the resistance of vaginal cicatrices—the utility of his teaching and practice in this regard being recognized by foreign obstetricians.

It is sad to recall the fact that this famous man, with whom the history of American obstetrics really begins, should ever have been an unsuccessful candidate for the chair of midwifery in the University of Pennsylvania;[3] sadder still to know that when, twenty-four years later, the honor came by unanimous voice of the trustees, failing health permitted him to hold it but a year—the infirmities of age are upon him, almost the shadow of the grave is in his path before he reaches the noble goal of his life, and grasps the coveted prize. How true it is that his

—"laurel crown
Rustled most when the leaves turned brown."

The next American work on Obstetrics was "The Philadelphia Practice of Midwifery," by Dr. Charles D. Meigs,[4] published in 1838; it was brief and elementary; a second edition was issued in 1842. Three years subsequently Dr. Meigs was elected a professor in Jefferson Medical College, and became famous as one of the best of teachers and one of the most brilliant of lecturers, while his genial manners in social life won all hearts. Almost equally fascinating with his uttered are his printed words, so that one can now read page after page until hours pass away without weariness. Fluency and force, strength and beauty, characterized his literary composition in a remarkable degree; not only

[1] It is stated by Hutchinson (Biographia Medica, London, 1799), that Smellie for a time endeavored to substitute wooden for steel forceps.

[2] In referring to Dr. Denman, Dr. Dewees remarks: . . "there was a time in my life when I looked upon Dr. Denman to be the highest authority in midwifery."

[3] The election of Dr. James seems really to have been effected by a combination between him and Dr. Chapman—there were only three candidates—the latter to have half the emoluments, and to succeed to the next vacant chair in the University (see Hodge's eulogium upon Dewees)—a sort of bargain and sale which at this distance does not seem quite immaculate.

[4] A very interesting memoir of Dr. Charles D. Meigs, by his son, Dr. J. Forsyth Meigs, has been published, but unfortunately did not come into the writer's possession until he was correcting the proof-sheets of this Address. In the memoir the author states that his father wished to call his home in the country "Paraclete," the Comforter. Was not this in imitation of Abelard, who, when his admiring students, following him to his desert retreat, built him a new oratory, called it the Paraclete?

the treasures of his favorite department were his, but he was at home in general literature and familiar with classic story, while a Gallic vivacity, if not a poetic genius, flashed out as he moved on his brilliant path, like the phosphorescent spray from a ship's prow as she ploughs the tropic seas.

In 1849, Dr. Meigs re-issued his work on obstetrics in a much enlarged and improved form; since that date four editions have been published, this fact indicating the great favor with which the American profession regarded it. The most valuable discovery in obstetric pathology made by Dr. Meigs is the usual cause of sudden death after delivery, which he announced in 1849. Before and since, various other explanations of this terrible accident have been given, such as the entrance of air by the uterine veins, nervous exhaustion, shock, puerperal poisoning, etc., but to-day the theory of Meigs has general professional acceptance, even if the heart clot, or pulmonary thrombosis, the immediate cause of fatality, should be proved to be itself a result of myo-cardiac[1] degeneration.

As we read how earnestly Dr. Meigs declares against Cæsarean section, save in the interests of the mother, we shall find additional reasons for questioning Dr. Smith's allegation as to American obstetrics being so much more nearly a product of French than of English teaching—the chief alleged characteristic of the French school being the proneness to sacrifice the mother's rather than the infant's life whenever the rights of the two are brought in conflict.

Dr. Meigs's views as to puerperal fever were boldly expressed, and no concealment of them is now required. The painter in the Sacrifice of Iphigenia simply drew a veil over the face of Agamemnon: Would that a veil had forever hidden, not the views of Dr. Meigs only, but of other teachers of the Philadelphia school, and many sacrifices, blinder, more terrible, might have been averted! He who held the non-contagiousness of measles, of scarlet fever, even, might also hold to the non-communicability of puerperal fever under all circumstances. To-day, at least, the American profession are generally agreed that while the disease is frequently auto-genetic, it sometimes at least, and in its most terrible forms, is hetero-genetic, and it is the merest *petitio principii* to allege, as Dr. Meigs did, that, because he did not know of his having communicated it, either by conveyance of the poison from one patient to another, or from autopsies, therefore this never happened to others.

In 1849, "A Theoretical and Practical Treatise on Human Parturition," by Professor Henry Miller, of the University of Louisville, was published. In 1858, a republication of this work, much enlarged and improved, was made. From Dubois, Dr. Miller took his anatomy, and from Dugès, his classification of presentations and positions, while his principles of practice were essentially the same as those of Burns and Hamilton. Dr. Miller's views in reference to the importance of inflammation of the lining membrane of the uterus as a frequent cause of abortion, were certainly in advance of obstetric writers of his day. So, too, the higher honor must be given of being the first American obstetric author who advocated anæsthesia in labor.

Dr. Miller was a man of vigorous mind; he was clear and original in thought, concise in expression, severe almost to bitterness in controversy.

[1] De la Myocardite Puerpérale, comme cause la plus fréquente des Morts Subites apres l'Accouchement. Par Maurice Coste. Paris, 1876.

Like Dr. Dewees, he had few early advantages in education, but he learned to use his pen with more ease and force than the latter, and probably was a man of better original endowments. His work on obstetrics was declared by the late Dr. Condie[1] to be a most able one, conferring the utmost credit upon the author.

The Principles and Practice of Obstetrics, by Gunning S. Bedford, M.D., Professor of Obstetrics in the University of New York, was published in 1861; and five subsequent editions have been issued. Dr. Bedford's volume, which is probably the most learned of American works on obstetrics, is in the form of lectures, and with here and there some extravagances in rhetoric, is written clearly, plainly, indeed sometimes assuming a colloquial style. It is evidently "the result of much labor and research."[2] From its long list of authors quoted, and from its full and carefully prepared index, it is admirable as a book of reference.

We find this author arraying himself on the side of the contagionists as to puerperal fever, but a rejector of anæsthesia in normal labor. His teaching as to the choice between craniotomy and the Cæsarean section is almost directly the opposite of that of Dr. Meigs and most other American obstetricians, and while he protests against craniotomy, he does not fully recognize that podalic version may be the true alternative, and not the Cæsarean operation.

In 1864, the most original and elaborate of American Obstetrical works was issued in Philadelphia, the admirable treatise of the late Dr. Hugh L. Hodge, the honored successor of Dewees in the University of Pennsylvania. After thirty-one years of obstetric teaching, he prepared this rich legacy for the profession.[3]

Dr. Hodge was the first to illustrate the peculiarities of the female pelvis, its axes and its planes, by taking a plaster cast of it, and making sections of the cast. He was the first to use photography,[4] to exhibit with perfect accuracy the relations of the fœtal head to the mother's pelvis, in the various presentations and positions, and in the different stages of simple and of complicated labor, and also the applications of the forceps in different positions. He contributed materially to restore the vectis to use in the remedying of malpositions. The application of the obstetrical forceps to steady and isolate the head, in craniotomy, then after the operation the use of the instrument for compression and extraction, must be regarded as a most valuable improvement, for which the profession is indebted to Dr. Hodge. He also improved the operation of cephalotripsy by devising a simple and efficient instrument —his compressor cranii. He taught the doctrine of synclitism, or parallelism of the plane of the child's head, in cases of natural presentation, to the planes of the pelvis and vagina, as early as the year 1832, and from that time until his death presented this doctrine with more precision and detail than has any other author. He was among the first to recommend the induction of premature labor, in cases where labor had previously terminated fatally to the child in consequence of its great size and the complete ossification of its head. His obstetric forceps is the one

[1] American Journal of the Medical Sciences, Jan. 1857.
[2] British and Foreign Medico-Chirurgical Review, July, 1862.
[3] "Dr. Hodge's treatise is, nevertheless, full of much valuable information, and although its price alone will prevent its ever becoming popular amongst students in this country, still we strongly recommend that it should have a place in the library of every obstetric physician."—British and Foreign Medico-Chirurgical Review, October, 1865.
[4] This was done at the suggestion of his son, Dr. H. Lenox Hodge.

held in most favor by the American profession. Few men have studied the mechanism of labor more thoroughly, none have expounded it more clearly. Generations may come and depart, until another century pours its treasures upon the race, but it is doubtful if among these will be found another work on obstetrics of greater relative merit and of more enduring value than the treatise of Dr. Hodge.

In the year 1870, a Treatise on the Theory and Practice of Obstetrics, by Dr. W. H. Byford, was published, a second edition appearing in 1873. The design of Dr. Byford was to furnish the student and busy practitioner with a more concise work than any in general use, and yet embodying all the necessary practical information. No one can question how well its able and industrious author has succeeded in this design.

A work entitled Elements of the Principles and Practice of Midwifery, by Dr. David H. Tucker, was issued in 1848. The Obstetric Catechism of Dr. Warrington was, in Philadelphia, held in high esteem twenty or more years ago, especially by those who were fortunate enough to avail themselves of the practical instructions of this excellent teacher. Dr. Cock's Manual of Obstetrics, 1853, was held in like favor in New York.

Having devoted so much space to the consideration of treatises upon obstetrics, the topics of obstetric pathology[1] and therapeutics must necessarily be briefly considered.

The present century has been marked by some of the most important advances in obstetrics; and "it is not going too far to assert that, notwithstanding the brilliant improvements in surgery, and the solid and wise modifications in medicine, the changes in our art have preserved more lives, and relieved more human suffering and misery."[2] In promoting these advances, and in effecting these changes, our country has borne her part. Few obstetricians of the present day would accept the statement of William Hunter, that upon the whole the forceps had "done more harm than good," or participate in the "doubt" of Denman "whether it would not have been happy for the world if no instrument of any kind had ever been contrived for, or recommended in, the practice of midwifery," or believe—and we quote again from Denman[3]—that "the doctrine of applying forceps before the bulk of the head has passed the superior aperture of the pelvis, carries great danger and insurmountable difficulties with it;" nor again, does the obstetrician now wait until he can "feel an ear," or until "the head has rested six hours upon the perineum," before resorting to an instrument that is at once for the good of both child and mother.

Anæsthesia in obstetricy must be counted one of the greatest glories of the century—nay, the brightest, broadest beam of perennial light that has ever fallen upon woman's pathway, darkened by the primeval curse. In 1846, the great discovery of anæsthesia by inhalation of ether vapor, with which the names of Wells and Morton are so inextricably inter-

[1] The topics of obstetric anatomy and physiology would be appropriate could their history be made really complete. Under the former head would be mentioned in detail Dr. Hodge's studies as to the female pelvis, already referred to; Dr. John Neill's, as to the shape of the thyroid foramen, and numerous similar investigations; and under the latter, studies such as Dr. Dalton's, of the *corpus luteum;* Dr. Geo. J. Englemann's recent, patient, thorough, and interesting researches as to the mucous membrane of the uterus; Dr. Isaac E. Taylor's demonstration of the non-shortening of the cervix in the latter months of pregnancy; and Dr. J. R. Beck's observations upon the entrance of the spermatozoa into the uterus.

[3] Criticism of Leake.

woven, was made; in January, 1847, the illustrious Simpson, of Edinburgh, proved the value of ether in child-birth. The discovery found Walter Channing, the first professor of obstetrics[1] in Harvard, past his three-score years; but he entered heartily into the study of this question, and the next year he presented a volume upon Etherization in Child-bed, in which the records of nearly six hundred cases were given, and which greatly contributed to the frequent—I wish at this day one could say *general*—use of anæsthetics in labor. Other names deserving of recognition in this connection are those of Drs. F. Barker, of New York; H. R. Storer, of Boston; J. C. Reeve, of Dayton, Ohio; and H. Miller and L. P. Yandell, of Louisville, Kentucky.

The administration of chloral is another of the beneficent means of recent times for the relief of the sufferings of parturition, which has had many advocates in this country.

The opium treatment of peritonitis is one of the most important advances in therapeutics. It may be now true, as asserted by Dr. Spender,[2] that "the bare mention of that terrible disease, peritonitis, is suggestive of the siren lullabies of opium." But this treatment was the suggestion and practice of Dr. Alonzo Clark, as early as 1841,[3] though it was not until 1848 that he had an opportunity of demonstrating its value in the puerperal form of peritoneal inflammation. Opium alone, is the treatment of *phlegmasia dolens* advocated by Dr. Clark,[4] of Oswego, and he claims that the remedy is as efficient as quinia in ague.

A marked advance has been made in the more liberal diet and rational hygiene of women after labor. That former horror of the lying-in room,

[1] This position Dr. Channing held for nearly forty years, and only a few weeks since passed away from earth, having lived to be upwards of ninety years of age.

[2] Therapeutic Means for the Relief of Pain. London, 1874.

[3] The following recent note from Dr. Clark will be read with interest:—

DEAR DOCTOR: I continue to use opium in the treatment of simple peritonitis and puerperal peritonitis, and peritonitis after perforation, with the fullest confidence that it will cure a much larger proportion of cases than any other treatment yet proposed. It is accepted by all the physicians of this city and State, I think; at least I hear of no other, not only for peritonitis in its different forms, but in all operations, injuries, and wounds that are likely to be followed by this inflammation. I do not know how far it is approved abroad, but infer that it has received little attention in England, from the fact that Dr. Barker, of this city, made it the topic of an address at a meeting of English physicians a year or so ago.

Dr. Graves, it is said, used opium in large doses for the cure of peritonitis after perforation of the intestine. When he began that treatment I do not know; but I do not find any reference to it in his lectures published in 1843. Watson's Lectures, one of the later editions, refers to a Mr. Bates, who treated peritonitis with opium; but when he began, does not appear. Still the English physicians generally seem to know little of the power of opium in the different forms of peritonitis. In the Am. Journ. of Med. Sci., July, 1876, p. 144, you may find a statement of the origin of this treatment in my own mind, in 1841; and before 1843 cases of intestinal perforation had been successfully treated on this plan.

Regarding the rules, I begin with two grains of opium, or its equivalent opiate, and in two hours give the same, or more, or less, according to the effects produced. Patients resist or yield to the narcotic effects of the drug very differently. In some cases, twenty-four grains of opium a day is all that is required; in a few, twelve or sixteen grains is sufficient. In most, two to four grains at a dose are needed; in a few, more than this. The aim is to get and maintain the symptoms of *safe narcotism*, or, as I sometimes call it, semi-narcotism, indicated by subsidence of the pain; contracted pupils; itching of nose and skin; a continuous sleep, from which, however, the patient is easily aroused; reduced frequency of respiration, followed by reduced frequency of pulse; and absolute quiet of the bowels.

Regarding the respiration, the aim is to reduce its frequency to twelve in the minute, and in the attempt to do this it is often found to fall as low as seven, without danger, if the opium is then withheld for a few hours, till it rises to ten, when a smaller dose is given, to be increased or not afterwards. Yours truly, A. CLARK.

[4] New York Medical Record, June, 1870.

the very existence of which is cast in doubt—milk fever—which was to be averted by a liberal use of the canonical caudles of Smellie's day, and the prophylactic panadas of more modern times, and by poisoned air, no longer governs practice; and the recent parturient is given cold water as she desires, inhales pure air, and is fed with wholesome food, that is, such as will best repair her exhausted powers and furnish suitable material for making good milk. How early any publications were made advocating this course, I cannot ascertain, but certainly it has been pursued for some years, and possibly it may not have been at the instance of any professional leader, but simply a general tendency of physicians themselves. The names of Drs. F. Barker, William Goodell, and William B. Atkinson, are among the more prominent of those who have advocated it.

During the present year a most able volume on Extra-uterine Pregnancy, by the late Dr. John S. Parry, has been published. In it the talented author, removed too early for the honors that surely awaited him, and for a career of great usefulness not half accomplished, has collected five hundred cases of this accident, and from a careful study of them has deduced most important practical rules. Such works are at once permanent contributions to medicine, and indices of its higher development and more scientific character.

Some of the most remarkable cases of operation for extra-uterine pregnancy are those by Dr. William Baynham,[1] of Virginia, who operated twice, 1791 and 1799, successfully by abdominal incision; one by Dr. John King, of South Carolina, 1813, who incised the vagina at full term, saving both mother and child, and one by Dr. T. G. Thomas, the pregnancy having advanced to three months, who also incised the vagina, but with the galvano-caustic knife. So, too, the case reported by Clarke, in 1806, where he passed his hand into the bowel, and with his finger in the child's mouth exerted such traction that he withdrew the head *per anum*, should not be forgotten among the extraordinary cases, especially as he thus showed the feasibility of the method of abdominal exploration recently proposed by Simon. Dr. Easley,[2] of Little Rock, Ark., has quite recently reported an interesting and successful case of abdominal section for the removal of a dead fœtus.

The Induction of Premature Labor was first resorted to in this country, in 1810, by Dr. Thomas C. James[3]—the cause, contracted pelvis, and the result fortunate to both mother and child. Since that time a much larger range has been given this operation. We have already stated Dr. Hodge's views as to its being indicated in cases where the head is large and completely ossified at full term. Dr. Thomas[4] has enumerated ten other conditions indicating it, the most important being placenta prævia and aggravated uræmia. The teaching and experience of Dr. Thomas have contributed much towards the recognition of the propriety of inducing premature labor, in the interest of both the mother and the child, in cases where the placenta is prævia. A distinguished British obstetrician[5] observes: "We have arrived at a very generally admitted conclusion as to

[1] Dr. William Baynham was long considered the most eminent surgeon in the Southern States, and was particularly distinguished for his accurate knowledge of anatomy.—Thacher's Medical Biography.

the danger of temporizing, and as to the advisability of artificially inducing labor as soon as the existence of placenta prævia has been fully determined." It is true Dr. Thomas's publication was in some measure anticipated some six years by a paper from Dr. Greenhalgh,[1] advocating this practice; but he himself was partially anticipated by Dr. A. S. Donkin,[2] who proposed to expedite labor and check the flooding in placenta prævia by inserting into the os uteri a sponge-tent prepared for the purpose. Dr. S. C. Busey,[3] of Washington, has presented an able argument for the induction of labor in uræmia.

Placenta Prævia has been the subject of special study by Dr. J. D. Trask,[4] and by Dr. Wm. Read.[5] Dr. Read was regarded by the highest[6] critical authority in Great Britain as having rendered valuable service to his profession, and considerably enlarged and strengthened the foundations of obstetric science; and it is declared that the impartial and philosophic manner in which he has used statistics for the purpose of deciding grave practical problems is worthy of all praise and imitation.

Dr. Trask, whose prize essay on placenta prævia has been alluded to, has also laid the profession under obligations by quite a thorough study of rupture[7] of the uterus; four hundred and seventeen cases of this accident are tabulated, and important lessons deduced. This monograph ranks by the side of the one by Crosse on uterine inversion.

Dr. John Stearns,[8] of New York, in a letter to Dr. Akerly, published in the Medical Repository, 1807, announced that ergot[9] was capable of exerting a specific action upon the uterus; that it greatly augmented the power of that organ during the efforts of parturition; and that, in lingering and protracted cases, it speedily induced forcible pains, and greatly expedited delivery. And in June, 1813, Dr. Oliver Prescott, in a communication made to the Massachusetts Medical Society, pointed out the value of this agent in *post-partum* hemorrhage. Thus the two most important obstetric uses of ergot were first made known by American physicians. An able paper, by Dr. William Goodell, on Concealed Accidental Hemorrhage,[10] was published in 1869. This paper contained an analysis of one hundred and six cases, and presented the symptomatology more clearly and definitely than had been done before. Diphtheria of Puerperal Wounds has been made the subject of important contributions by Drs. Lusk and Parry.

We now make some brief references to operative obstetrics, including both manual and instrumental.

One of the most valuable contributions to obstetric art ever made was

[9] *Pulvis ad partum* was the name soon appropriated to the powdered ergot. Hosack, however, shortly substituted for it, *Pulvis ad mortem*. This is suggestive of Guy Patin's remark in regard to an antimonial preparation which was in great favor in his day, known as the *Vinum vitæ*. In one of those letters, first published at Geneva, 1683, of which Voltaire has observed, "they were read with eagerness, because they contained anecdotes of such things as every body loves, and satires, which are liked still more," Patin writes that the *Vinum vitæ* should be called *Vinum mortis*.
[10] American Journal of Obstetrics, August 1869.

that of Dr. M. B. Wright,[1] of Cincinnati, in the year 1854. To him is justly due the credit of originality in the method of such bimanual operation as will in shoulder-presentation succeed in converting it into a presentation of the head. Even if the method of Wright were precisely the same as that of Hicks,[2] still it was published six years before. But the essential of each is in the use of both hands—the external hand, not as by former operators merely to steady the uterus, but to assist the action of the other. True, Dr. Wright applied the method only to what is called cephalic version; Dr. Hicks gave greater prominence to the accomplishment of podalic version.

Next among important manual operations must be placed the postural treatment of prolapsed cord and of shoulder presentations, known in its first application as the method of Thomas, in its second as that of Maxon. In foot-notes I have given extracts from the original work of Deventer, conclusively showing that this treatment was advised by him, though it was pressed with no urgency, and seems to have been theoretical rather than supported by clinical facts. Dr. Bard, in considering podalic version in presentations of the breast, belly, and back, says expressly: "And in all cases of particular difficulty, we may facilitate the operation by a judicious choice of the posture of the woman; or by changing it from the side to the back, or from the back to the knees and elbows. Deventer particularly recommends this position." No one in the face of these testimonies can doubt the priority of the Hollander in the suggestion of postural treatment in these labor-complications. So, too, in Dr. Wright's essay, already referred to, the suggestion of the knee-elbow position is made. Nevertheless, to Dr. Thomas, of New York, and to Dr. Maxon, of Syracuse, is due the credit of having demonstrated by abundant clinical facts the great value of this method in prolapse[3] of the cord, and in transverse presentation, and of establishing it in professional confidence.

A passing notice is due Dr. Goodell's "Management of Head-Last Labors,"[4] in which constant supra-pubic pressure conjoined with continuous traction may so expedite delivery as to greatly diminish fœtal mortality; and Dr. Parry's[5] method of correcting with the hand faulty presentations and positions.

In obstetric surgery no country can claim more brilliant operations than those of the late Dr. William Gibson, Cæsarean section twice successfully performed upon the same subject, the children also saved, and the gastro-elytrotomies of Thomas and Skene.

Of course it is impossible to refer to even a tithe of all the valuable American contributions to obstetrics and puerperal diseases in the limits of this Address—a simple bibliography would consume more than the time allotted it; and a dictionary of dates, with a catalogue of cases, would illy meet the requirements of the occasion. Nevertheless, three contributions in this department demand special notice.

In the year 1843, Dr. Oliver W. Holmes published, in the New England

[1] Prize Essay. Ohio State Medical Society. "Difficult Labors and their Treatment."

[2] Dr. Hicks published his method in the Lancet in 1860, giving five cases of placenta prævia in which he had resorted to bimanual version, and in 1863 (London Obstetrical Society's Transactions, vol. v.), presented a fuller account of it.

[3] Prolapse of the cord has been made the subject of an elaborate monograph by Dr. George J. Englemann, American Journal of Obstetrics, 1873–4.

Quarterly Journal of Medicine and Surgery, a paper afterwards issued in book form, in reference to the contagiousness of puerperal fever. Empedocles combined in one, poet, priest, politician, and physician; and history records that he rescued a city from desolation by blocking up a mountain gorge through which pestilential winds were sweeping. In like manner an American, whom the world so knows as poet, essayist, and philosopher, that, arrayed in these glories, crowned with these honors, we almost forget that he is a physician and medical teacher, once by his bold, decisive utterances, his startling array of facts, his invincible logic, greatly contributed to destroy a pernicious doctrine taught by some of our leading obstetric authors—a doctrine which was more certainly laden with death than the foul wind that was destroying the citizens of Agrigentum.

In 1868, the Obstetric Clinic, a Practical Contribution to the Study of Obstetrics and the Diseases of Women, by Dr. George T. Elliot, was published. Its author, whose talents and culture were admirable, and who, alas, was taken away in the prime of life and power, utters these noble and just words explaining his motives in writing this book, words which ought to be well pondered by all who have similar opportunities. "The work is presented as a partial discharge of the debt due to the profession by all who enjoy hospital advantages; and in grateful recognition of the benefits which the author has derived from the experience of others." Elliot's Obstetric Clinic has taken its place among the classics of our profession, and cannot fail to be of value to any one who consults its pages.

In 1874, the first edition of Dr. F. Barker's Lectures on the Puerperal Diseases was issued, and the second edition the present year. This, too, is a clinical work, and eminently practical. It filled a gap in medical literature, met an urgent need of the practitioner, and was received with great favor, both at home and abroad.

In considering the second division of the subject, an order similar to that observed in the first will be pursued, and accordingly American treatises on Diseases of Women will first be referred to. These works have had the following authors: Dewees, Meigs, Hodge, Byford, Chapman, and Thomas. The first edition of Dewees's work was issued in 1826, the ninth and last in 1847; this contains the revisions and additions made by the author a short time before his death, and may be regarded, therefore, as embracing Dr. Dewees's best utterances upon the subjects discussed in it. To say that the book is badly written, would be a mild way of stating that there are therein frequent instances of violations of the simplest rules of grammar and the plainest laws of rhetoric. But what of the matter? More than one-third of the five hundred and odd pages are occupied with the disorders of pregnancy, puerperal fever, phlegmasia dolens, milk abscess, and hysteria; diseases of the ovaries are discussed in a little more than a page, and the moderately well-behaved irritable uterus of Gooch, becomes a monster of inflammation for the conquering of which general depletion is sometimes, and local depletion is always, necessary. On pages 256 and 257, there is given the history of one of the most strangely managed cases, as seen by the light of to-day, that ever was recorded. In brief, nature tried to extrude from the vagina a uterine fibrous polypus as large as a child's head, and the doctor with might and main resisted, but vainly, the extrusion; and then, instead of dividing the short, thick pedicle, he tried to push the tumor back because the womb was inverted; but the

tenderness of the parts prevented, the tumor became black and offensive, and the next day the patient died.

However, Dr. Dewees did advance the knowledge of the profession in regard to the symptoms of uterine displacements, and the means for relieving them; he taught when and how to use tincture of cantharides in amenorrhœa, and his name will not be forgotten as long as dysmenorrhœa ever suggests the ammoniated tincture of guaiacum. But Dr. Dewees's great fame is that of an obstetrician, not a gynæcologist.

Woman, Her Diseases and Remedies—the work of Dr. Charles D. Meigs—was issued in 1847, and the fourth edition in 1859. The volume is in the form of letters, and, of course, less dignity of style and greater freedom of expression are permitted than in a purely didactic treatise. Here are not only sketches of disease, but also lessons of high morality, of professional honor, and of tender sympathy; here are odd words and odd forms of expression; sometimes ludicrous dialogues, in which refinement and dignity are thrust in the background by realism; a fluent stream, apparently wandering at its own sweet will—now rippling with music and sparkling with sunshine, here narrow and strong, there diffuse and almost wearisome in its slow progress—but still always advancing, and strengthening in the advance; or a picture-gallery (and the æsthetic element in his nature was so strong that, possibly, Dr. Meigs might have been a great poet, or a great painter, had he not been a great physician), in which various representations, persons and scenes are collected, some altogether mean, and given with painful minuteness of sketch and color, others noble in conception and expression, but each filling a destined place, all real, vivid, and combining in a common design and purpose—such are these Letters that never lose their charm. Dr. Condie, who had no patience with anything but the plainest English, severely criticized in the American Journal of the Medical Sciences the style of these letters. But the style was the man; the letters are not less his teachings than they are Dr. Meigs himself.

Undoubtedly the instructions of Meigs were very much in advance of those of Dewees. Was he not, too, the first American at least to describe vaginismus under his horrible designation of sphincterismus? He hated abdominal surgery, and so rejected ovariotomy; cervical surgery, too, and so in stenosis adhered to Mackintosh rather than to Simpson; he clung with devout faith to Gooch's canula in the removal of uterine polypi, and regarded complete perineal ruptures as incurable.

Clinical Lectures on the Diseases of Women and Children, by Dr. Gunning S. Bedford, were published in 1855, the seventh edition in 1862. To this work was paid the high compliment of translation into French and German. With much that is valuable even to-day, and impressively given, there are some things that would be utterly rejected as rules of practice. For example, who would now think of salivating a patient because she had ovarian dropsy, or expect such dropsy to disappear under the magnetic influence of "patting the tumour with the ends of the fingers several times during the day, together with pressure, and the internal administration of muriate of lime." The author's utterances, too, as far as manner is concerned, are at times either simply grandiloquent, or degenerate into tedious and undignified dialogues, or trite commonplaces.

A far better book than any of those yet referred to is the Practice of Medicine and Surgery applied to the Diseases and Accidents incident to Women, by Dr. William H. Byford, published in 1865. Its great merit

is its evidence of faithful observation and reflection; it was the work of a painstaking, conscientious man with large experience, and it has contributed much to the promotion of a knowledge of diseases of women among the American profession. Dr. Byford (p. 348) has proposed and practised an original method of treating uterine fibroids, which is probably deserving of more professional attention than it has received, and he also first made use of tents of slippery elm. Dr. Byford speaks of the "philosophy" of uterine displacements, and in the misuse of this term[1] has been imitated by some others: would it not be quite as correct to speak of the philosophy of boot-blacking or of coat-cutting?

Diseases Peculiar to Women, by Dr. Hugh L. Hodge, the first edition in 1860, the second edition revised and enlarged in 1868, and Hysterology, by Dr. E. N. Chapman, New York, 1872, are two works diametrically opposed to each other, or at least presenting entirely different theories of uterine disease. Dr. Chapman's pathology is congestion, and his local therapeutics are chiefly scarification and nitrate of silver; where pessaries are required, preference is given for those that are globular, and appropriate constitutional treatment is directed. His work is largely clinical, though unfortunately most of his reports of cases are too brief to be of great utility. Dr. Hodge, on the other hand, taught that the condition of uterus characterized by tenderness, congestion, increase of secretion and of size, was not inflammation, and should not be so treated. Here was the irritable uterus rescued from the inflammation of Dewees which was devouring it, and restored to the position which Gooch and Addison meant to assign it; nay, given an importance and extent in uterine pathology which they could hardly have anticipated. According to Dr. Hodge, "displacements of the uterus are the most frequent cause, original or secondary, of irritable uterus;" and "the mechanical treatment of uterine displacements by intra-vaginal supports is essential, a *sine quà non* for their perfect relief."

Whether accepting in full, or only in part, the views of Dr. Hodge upon uterine pathology, no one can deny the great service that he rendered uterine therapeutics in the device of his lever pessary, an instrument in such common use in all lands where diseases of women are studied. His pessary was no happy accident, but the result of much thought and of many experiments; as he himself once expressed it, he had hundreds of abortions before producing it. "Great poetry, great philosophy, great scientific discovery, every intellectual production which has genius, work, and permanence in it, is the fruit of long thought, and patient and painful elaboration."[2] Not only with the form of the pessary, but with the material, is Dr. Hodge to be credited. No man ever accomplished as much with these instruments, or explained their modes of application and their utilities more clearly and completely. He showed their value not only in relieving the ordinary results of uterine displacement, but also in curing sterility, and in the prevention of abortions when these, too, were consequences of such mal-positions. So, too, he demonstrated their value as repositors, gradually replacing the uterus when in mal-position. He

[1] Sir William Hamilton, Discussions on Philosophy and Literature, remarks upon the vague universality which is given to the terms *philosophy* and *philosophical* in common English—an "indefinitude" limited especially to Great Britain: "Mathematics and physics *may* here be called philosophical sciences; whereas, on the Continent, they are excluded from philosophy, philosophy being there applied emphatically to those sciences which are immediately or mediately mental."

[2] Froude's Address to the Students of St. Andrews, March 19, 1869.

showed how useful they were, too, in relieving some of the urgent symptoms of uterine fibroids.

But the American work on diseases of women most widely known is the Practical Treatise of Dr. T. G. Thomas, published in 1868, and passing to its fourth edition in 1874. As a clear, concise, and practical exposition of gynæcology, it has no superior. At home, its merits have been so fully appreciated by the profession that nearly twenty-five thousand copies are now in their hands, helping them in their daily work—a success which, when we compare it with that of even popular[1] literary productions, is simply astonishing. Abroad, its great merits have been fully acknowledged by the leading journals of the profession, and it has been translated into French, German, Spanish, and Italian. Some of Dr. Thomas's views as to uterine diseases, and some of his special contributions to gynæcology, will be referred to in the next topics presented.

Laying aside the briefer mongraphs, whether appearing in the form of reports in the Transactions of Medical Societies, lectures, addresses, etc., the *libelli* of our literature, and contributions to our medical journals—all these numbering not merely hundreds but thousands, and of course an analysis of which, even if it might be instructive, would be impossible —four works relating to diseases of women, demand especial attention. These are Clinical Notes on Uterine Surgery, by Dr. Sims (New York, 1869); Vesico-Vaginal Fistula, by Dr. Emmet (New York, 1868); General and Differential Diagnosis of Ovarian Tumors, by Dr. Washington L. Atlee (Philadelphia, 1873); and Ovarian Tumors, their Pathology, Diagnosis and Treatment, especially by Ovariotomy, by Dr. E. Randolph Peaslee (New York, 1872).

The Uterine Surgery was published not only in New York, but also in London, and a French translation appeared in Paris. It met, as it deserved, with much favor at the hands of the profession, although some parts of it did not escape[2] severe criticism. One of the leading British journals[3] spoke in these terms of the book: "It is a collection of bedside studies of the uterine diseases of which it treats, notable for their accuracy, and continually challenging our admiration for the sagacity and originality of their author, the fertility of resource, the unfailing patience, the successful adaptation to new purposes of simple means, the exact perception and clear statement of the vital points of every case." "For the first time in the history of medicine, the sterile condition is here subjected to a full and philosophical analysis, complete as far as the advanced knowledge of our time permits."

Dr. Emmet's work on Vesico-Vaginal Fistula was essentially clinical in character, the history and treatment of the seventy-five cases given, representing the author's own invaluable experience. "The results of the numerous cases related are in the highest degree honorable to Dr. Emmet's skill as an operator, and also to American surgery."[4]

Of the two admirable volumes upon Ovarian Tumors referred to, one embodies the thirty years' experience of a surgeon who ranks as one of the world's most celebrated ovariotomists, and is a treatise upon the general and differential diagnosis of these tumors. The other is more ambitious in design, and wider in scope. More largely a work of com-

[1] Mark Twain's Innocents Abroad, for example, has reached a sale of two hundred thousand.

[4] Lancet, February 20, 1869.

pilation and of analysis, than a record of personal experience, it exhibits the indefatigable research, the patient investigation, and the accurate judgment of its scholarly and erudite author. Without being encumbered, or possibly for some enriched, with so many details, it has much of the encyclopedic character of Gallez's volume,[1] and not only is a most useful guide in the diagnosis and treatment of ovarian tumors, but is valuable for reference.

Special contributions to gynæcology, other than those just referred to, can be better considered under the heads of particular disorders. But before entering upon this division of our subject, two or three preliminary observations may be permitted.

The first is, that while in this country specialism in other departments of medicine has made rapid progress, in gynæcology few, and until quite recently only two, specialties are found. And this arises from the fact that the diseases of women must, in the nature of things, be chiefly under the charge of the general practitioner. What is the numerical relation between those diseases that are constitutional in their origin and amenable to general treatment, and those that are local and require local treatment, is a question that would have different answers, according as addressed to the general or the special practitioners. That there were extreme surgical tendencies of uterine pathologists, was the complaint a few years since of one[2] of the most eminent of British gynæcologists; and that this is true to-day, in this country, will be very generally admitted. There is something so fascinating in surgery, so demonstrative and demonstrable—that which the eye can see and the fingers touch—as to inspire the operator with ambition and the patient with hope.

Undoubtedly the danger of specialism is an undue exaltation of local disease and of local therapeutics. The general practitioner, on the other hand, is liable to depreciate the former, and then of course the latter. He does not extend himself, as Mill said of Jeremy Bentham, infinitely in one direction, but must be many-sided, undergoing a more general and complete development. Thus, other things being equal, he will be better able to detect the relations between local and general disorder, what in a given case is the antecedent and what the consequent, what may be cause or effect, unless indeed the specialist, as I believe is true of all who are devoted to gynæcology in this country, has chosen his department after large experience in general practice. The pine in our Southern forests grows stately and tall, lifting its tufted head far up to the clouds, but it is almost bare of boughs, and barren of foliage and fruit. "The unwedgeable and gnarled oak" is knit together with a stronger fibre. More firmly rooted, it spreads broadly on every side great branches, with dense foliage, ample shade, and abounding fruit.

The American development of gynæcology has been largely due to the labors of men engaged in general practice. Considering now that development, brief reference will be made first to the treatment of some of the positional disorders of the uterus.

The pessary of Hodge has already been spoken of; an instrument which, both as to form and material, has received the general and grateful acceptance of the profession everywhere. Modifications or additions, more or less valuable, of the lever pessary have been made by Drs. Albert

[1] Histoire des Kystes de l'Ovaire, etc. Brussels, 1872.
[2] Dr. E. J. Tilt. Transactions of the London Obstetrical Society.

H. Smith, Cutter, Thomas, and others. Nor must we omit, in this connection, a passing reference to the very interesting observations of Dr. H. F. Campbell, of Georgia, upon pneumatic pressure in the treatment of uterine displacement.

Turning to the greatest of all the positional disorders of the uterus—inversion—we will find that American operators may challenge comparison with those of any country in regard to ingenuity, skill, and success in its cure.

Inversion of the uterus,[1] an accident first noticed by Celsus,[2] was, until quite recently, an opprobrium of the profession, since replacement of the organ, unless efforts were made almost immediately after the accident, was regarded as impossible. The few instances where a chronic inversion was reduced, were regarded as happy accidents rather than as indicating a rule of practice. On April 13, 1858, Dr. Tyler Smith observed, in reporting to the Medico-Chirurgical Society[3] a case of uterine inversion of nearly twelve years, which he had reduced: "Hitherto inversion of the uterus has been treated either with styptics and astringents, or the inverted organ has been removed by ligature or excision. The instances in which reinversion has been accomplished have been few in number, and chiefly limited to cases of recent origin." On the 12th of March of the same year, Dr. J. P. White,[4] of Buffalo, reduced an inversion of nearly six months' duration. The one used elastic pressure and taxis; the other taxis and pressure[5] with a bougie. These successful cases were the heralds and guides of numerous similar successes at home[6] and abroad.

In this country the most important new methods of accomplishing reduction were that of Noeggerath, indenting one or other or both of the cornua, and thus starting the movement of restoration; that of Emmet, using silver sutures to hold in place a partial reduction; and those of Thomas, consisting, the one of *mediate* dilatation with a boxwood cone pressed down from the abdomen into the constriction, the other of abdominal section, and then *immediate* dilatation; and the repositor of Dr. White. Abdominal section, with immediate dilatation, has been twice performed—once with complete success, and once with a fatal result—but fails of professional endorsement. The repositor of Dr. White is an admirable instrument, as any one who has ever used it faithfully will testify: no one comparing it with the "drum-stick" repositor of Depaul

[1] Dr. Isaac E. Taylor has proposed and ably sustained the view that spontaneous inversion of the uterus sometimes commences at the os; a view which is strengthened by the cases of spontaneous reduction, the most extraordinary of which has recently been reported (American Practitioner) by Dr. Chesnut, of Lafayette, Ind. In Dr. Chesnut's case the restoration was twelve years after the accident.

[2] I am indebted to Dr. J. S. Billings for the following reference: Celsus, A. Cor., Medicinæ Libri Octo; Ed. by A. Lee, London, 1831. Lib. I. Præfatio, p. 15. "Cum aetate nostra quaedam, ex naturalibus partibus carne prolapsa et arente, intra paucas horas exspiraverit; sic ut nobilissimi medici neque genus mali, neque remedium invenerint. Quos ego nihil tentasse judico, quia nemo in splendida persona periclitari conjectura sua voluerit; ne occidisse, nisi servasset, videretur," etc. I find that several have commented on this passage, and especially Morgagni, who decides it to be a case of inversion of the uterus. Respectfully and truly yours, J. S. BILLINGS.

[3] Medico-Chirurgical Transactions, vol. xli.

[4] American Journal of the Medical Sciences, July, 1858.

[5] Dr. Thomas is in error when he states (Diseases of Women) that taxis alone was used by Dr. White, as can be seen by reference to the original account of the operation.

[6] Dr. White has been successful in twelve cases, and in one of the twelve the inversion had existed for twenty-two years.

would hesitate to give a decided preference to the former. Its value will become more and more appreciated as its use becomes more general.

Two of the most useful therapeutic agents in uterine disease, the one suggested by Dr. Sims, the other by Dr. Emmet, are among the simplest, viz.: glycerine[1] and hot water.[2] Dr. Emmet began the use of hot water injections in 1859, and observes, "I have been so thoroughly identified with this mode of practice, that it seems scarcely necessary to claim the priority. Certainly, no one in this country is on record as an advocate for the practice previous to myself; and so far as I have been able to ascertain, the same is true in regard to the practice of gynæcologists abroad." Confirmatory of Dr. Emmet's views as to the action of hot water injections in producing contraction of bloodvessels, and therefore useful not only in uterine, but also in pelvic, congestion, and in threatened cellulitis, was the practice of Trousseau[3] in menorrhagia—frequently directing two or three very hot injections daily. If Dr. Emmet had done nothing beside this, his name would deserve to be one of the most honored of the century in medicine.

Since the invention of the hysterotome by the illustrious Sir James Y. Simpson, and of its many modifications or substitutes by others, the cervix uteri, relieved from the potash-persecutions which, carried on by the ultra followers of Dr. Henry Bennet, a few years ago, threatened its integrity, has been made the subject of numerous cutting operations for the relief of dysmenorrhœa, or of sterility. Those who have contributed most to the practical study of these operations are Drs. Sims, Emmet, Pallen, Peaslee, and Worster, of New York, and Reamy of Cincinnati. There is something wonderfully fascinating both for surgeon and patient, when the former can carry salvation from dysmenorrhœa, and also a baby, upon the sharp edge of a bistoury, or between the blades of scissors! Unfortunately a conflict exists, both in theories and in experiences, as to the utility, the modes of, and the cases for, operation. It is to be hoped that since the recent publication of Dr. Peaslee, so conservative in its character, there will be elicited such discussion as will fully present the truth in this matter, and firmly establish practical rules for general professional guidance.

In amputation of the cervix uteri the flap method of Dr. Sims, and the use of the galvano-cautery of Dr. Byrne, are worthy of remembrance. Fluid applications to the lining membrane of the uterus are regarded by the profession everywhere as of great utility; and the safest and most common way of making such applications is simply one in close imitation of that originally devised and practised by the late Dr. Henry Miller,[4] of Louisville, Ky., more than a score of years ago.

Uterine fibroids in their frequency, in their exacting symptoms, in their sometimes apparently capricious history, and in the utter uncertainty of therapeutic means pursued for their relief, have long presented to the gynæcologist a field at once inviting and repellant. Electrolysis, studied in this relation by Neftel, Sims, Cutter, Kimball, and some others, cannot yet be said to have been admitted to professional confidence. Dr. Byford has ably collected most of the experience of the profession of this

[1] Sims's Uterine Surgery, pp. 21, 72.
[2] New York Medical Journal, June, 1874.
[3] Nouveau Dictionnaire de Médecine et de Chirurgie Pratiques, vol. xxii. p. 452.
[4] Others whose names might be mentioned in connection with the study of means for making such applications are Emmet, Lente, Nott, and Reamy.

country in the hypodermic use of ergot of Hildebrandt. But this treatment frequently fails, and the knife is occasionally required.

Those whose names in this country are especially identified with operations for the removal of these tumors, are Dr. Atlee,[1] Dr. Sims, and Dr. Emmet. The most valuable original observation belonging to the last is the pedunculization of a fibroid which can be effected by traction. The important operations performed by the others, and the ingenious instruments devised for this by Dr. Sims, almost as prolific of instruments as Hudibras[2] of tropes, we pass by with this brief reference.

Removal of the uterus by abdominal section has been performed several times in this country, but most of these operations have not been successful. Probably the first case in this country, certainly one of the first, was that of Dr. Thomas G. Prioleau,[3] of Charleston, S. C., in the year 1819. The tumor, prior to the operation regarded as malignant, was very large, its removal with the uterus attended with much hemorrhage, and the patient died in twenty-four hours. On the 16th of April, 1850, Dr. Paul F. Eve removed the uterus for malignant disease, and the patient lived for between three and four months. The operation has, however, been done on account of fibroid disease, with permanent recovery, by the Atlees, Burnham, Kimball, H. R. Storer, Thomas Wood,[4] and some others.

Removal of the prolapsed uterus—the vaginal operation—has several times been successfully performed. One of the most interesting of these cases is that of Dr. S. Choppin, of New Orleans. The doctor, in 1861, removed not only the uterus, but with it the left ovary and Fallopian tube, which were also prolapsed, and the patient rapidly recovered.

Many other topics in this division are suggested, but only two can be considered as the greatest glories of American gynæcology, the operation for genito-urinary fistula, and that for the removal of ovarian tumors. Holding up these to the world, she may, with just pride, exclaim: These are my offerings to Humanity and to Medicine! Yea, these are MY offerings!

But is not the operation for genito-urinary fistula a triumph of American surgery? Up to less than a quarter of a century ago, how deplorable the condition of the unfortunate woman suffering from such a lesion! She had entered upon all the remaining sad and weary years of her life, through a portal over which surgeon and obstetrician alike had, time and again, witten: Let her who enters here dismiss hope. If here and there, now and then, a case was cured, the result was the exception, failure the rule. If Jobert, for example, cured some, his operation always failed in the hands of others. Now, how changed! An operation, known abroad as the American method, rescues these unfortunates from their infirmity, and restores them to society. Failure is now as rare as success was formerly.

Of course surgeons had come to apprehend the principles, before they had attained the method of cure.

[1] Transactions of the American Medical Association, 1853.

[2] "For rhetoric, he could not ope
His mouth, but out there flew a trope."

[3] Dr. Prioleau graduated in Philadelphia in 1808. Drs. Samuel Jackson and W. P. C. Barton were classmates. At the organization of the Medical College of the State of South Carolina, in 1824, he became Professor of Obstetrics, and filled the chair for many years. I am indebted to Prof. J. Ford Prioleau, the present occupant of the chair, for the statements given.

[4] Dr. Wood's cases are seven, with three recoveries.

For the closure of these fistulous openings two things were necessary. First, their margins must be thoroughly and uniformly freshened. Second, this vivification accomplished, the freshened surfaces must be brought and retained in accurate apposition until union took place. But how should these edges be pared so completely and accurately? The first step for the accomplishment of this end was their thorough exposure. This step was taken in the position and speculum of Marion Sims. Here we have the very foundation of the operation. This fixed, knives of various angles, forms, and sizes, or curiously curved scissors, became mere minor matters, resting with the individual operator, or determined by the exigencies of each individual case.

But how are the prepared fistulous margins to be brought and kept in contact until nature binds them fast? Here again we hear, in 1852, the voice of Marion Sims crying, and crying aloud and on, until the whole world has heard Silver Sutures. Am I told that a British surgeon, in 1834, using silver gilt sutures, cured a case of vesico-vaginal fistula? He did not follow up this one success, and confirm it by others. He established no rules of practice, he instituted no method, and his report was unnoticed, it was as the voice of one crying in the wilderness. That one success, too, was it any more than an American, Mettauer, of Virginia, had gained in 1830, with lead sutures? Was it as much as Hayward, of Boston, accomplished with silk sutures? But are the brilliant results which Simon obtains, adduced to disparage the American method? Simon's operation has become the property and the practice of the profession scarcely more than Jobert's. We gratefully record the statement of one of the most eminent of French gynæcologists, Courty,[1] that the American school has no higher claims to future celebrity than the operation for vesico-vaginal fistula.

It is needless to mention the various modifications made by Dr. Sims in his original operation, or the valuable improvements introduced by Dr. Emmet, or the peculiarities of the method of Dr. Bozeman, who has labored with such signal zeal and ability, both at home and abroad, in this department of surgery, or the additions made by Dr. Mastin, of Alabama; or by Dr. Schuppert, of New Orleans; or by Dr. Battey, of Georgia; for the American method remains essentially that of Dr. Sims. Nor is it necessary to speak of Dr. Sims's early trials, patient perseverance, and triumphant success in working out the great problem to which, more than thirty years ago, he devoted himself with all that he had. The world knows them, and he has received honors such as have been accorded to few representatives of American Medicine.

A beautiful fable of the old Greeks made Apollo, the god of healing, give to the laurel tree its evergreen leaves, and consecrate them as crowns for the brows of victors. And surely who so worthy of the present of these crowns as a son of Apollo, who, after years of bitter struggles, has gained a victory which has brought blessings to thousands, and will bring them to tens of thousands more?

Is not ovariotomy one of the rightful glories of American gynæcology? What are the facts? In the year 1809 a village doctor of Kentucky successfully removed an ovarian tumor, and from that time until his death in 1830, operated in all thirteen times with eight recoveries[2]—a success, by

[1] Traité Pratique des Maladies de l'Uterus.

[2] For the collection of Dr. McDowell's cases, the profession is indebted to Prof. S. D. Gross.

the way, which, compared with the first thirteen cases of Baker Brown, or Spencer Wells, is most extraordinary. Spencer Wells, whose operations began in 1857, lost four out of the first thirteen, and Baker Brown lost eight out of his first thirteen.

Is the priority of Ephraim McDowell as the first surgeon to remove the diseased ovary invalidated by the case of Houston, of Glasgow, in 1701? All other claims to priority have been swept away as blunders or shams, and this, too, would need no notice, had not Dr. Washington L. Atlee republished it as a proof that ovariotomy "originated with English surgery," and had not Spencer Wells asserted that it "undoubtedly strengthens the claims of British surgery to the honor of originally practising ovariotomy."[1] It is strange that this case, rejected by Boinet and Clay,[2] should be now adduced. The operator simply incised a cyst and evacuated its contents. He no more performed ovariotomy than he who lances a suppurating parotid has extirpated the gland. The claim of British surgery to the honor of originating ovariotomy is weak beyond expression if it rests upon this case.

Again we are told, "But the operation was suggested by William Hunter; its practicability and the mode of performing it were taught by John Bell." William Hunter said: "I am of opinion that excision can hardly be attempted." He adds, however: "If we could beforehand know that the circumstances would admit of such treatment, the incision should admit of only two or three fingers, and the cyst be tapped and drawn out, that the surgeon may cut the pedicle without introducing his hand." But Tozzetti,[3] in 1752, Vanderhaar and Delaporte, in 1752, and Morgagni, in 1761, gave more encouragement to ovariotomy than did William Hunter; some of them as much, indeed, as John Hunter did, in 1786. The suggestions of Hunter and the instructions of Bell doubtless had an important influence upon McDowell's mind, but this detracts nothing from the glory of his achievement. The fame of Columbus is not dimmed by the fact that others before him, others in his time, believed with him that by sailing westward a sea-way to the Indies would be found. No matter what surgeons may have believed and suggested as to removal of diseased ovaries, no matter though John Bell taught the mode of operating, their faith without works was utterly dead, and the new Columbus started upon his exploration without pilot or chart.

But then, declares Nélaton, McDowell's first patients were negresses, and Gallez follows him, adding that his effort was to save the lives of slaves, who at that time commanded a high price, so that surgery owes this brilliant conquest to the cupidity of planters. How strange that historical facts of the present century can be so misrepresented. The truth is, that Dr. McDowell's first patient[4] was not a colored woman, but one of his own race and social position.

[1] Diseases of the Ovaries.

[2] Comme le fait judicieusement remarquer Boinet, après J. Clay, il y a eu simple incision du kyste, qui n'a été lié, ni excisé: on ne peut donc voir là une opération d'ovariotomie proprement dite. Gallez, op. cit.

[3] Gallez, op. cit. p. 404.

[4] This was Mrs. Crawford, who, after the operation, resided for a time at Madison, Ind. From the late Dr. Speer, of Hanover, Ind., who, when a young man, was for a time a member of her family, I received some years since a statement as to the efforts made by Dr. Ephraim McDowell's nephew to wrest the honors of the operation from the uncle. A lawyer from Lexington, Ky., visited Mrs. C., urging her to sign a paper stating that the nephew was the operator. Her reply was that she was blindfolded, and could not positively assert that Dr. Ephraim McDowell was the operator, but that she never would have consented to the young man's operating.

Surely British surgery has glory enough in the splendid successes of Spencer Wells and Keith, and the French in those of Péan, without either abating one jot or tittle of the fame of Ephraim McDowell.

Only sixty-five years since the performance of his first ovariotomy, only fifty-eight since its publication, and then many years before general professional recognition of the operation as legitimate, and probably it is not extravagant to assert that more than two thousand women have been by it rescued from impending death! Dr. Peaslee, writing in 1872, concluded, from a careful calculation, that ovariotomy had, in the United States and Great Britain, within the last thirty years, added more than thirty thousand years to the active life of woman. We may, indeed, assert most unequivocally that the name of the father of ovariotomy is worthy of being recorded with those of the best benefactors of the race.

Dr. McDowell's third ovariotomy was in 1816. In that year, or in the one preceding, Dr. Thomas G. Prioleau, whose extirpation of the uterus has already been referred to, assisted by his nephew, Dr. Philip Prioleau, and Dr. Frost, attempted ovariotomy, but was compelled by extensive adhesions to abandon the attempt; he therefore simply evacuated the cyst, and excised a portion of it. The patient died. Dr. Nathan Smith, of Connecticut, Dr. Alban G. Smith, of Kentucky, Dr. David L. Rogers, of New York, and Dr. Billinger, of South Carolina, are among the early American ovariotomists. To give a list of those who have operated since, including as it would numbers of the profession in almost every State in the Union, and in some more than a score of them, is impossible. Those who have operated most frequently are Atlee, Kimball, Dunlap, Burnham, Peaslee, Thomas, White, Sims, and Bradford. The last named, the late Dr. J. T. Bradford, of Augusta, Ky., had a higher percentage, no less than ninety per cent., of recoveries than any other operator in the world. Those who have contributed most, by the publication of statistics of the operation, or arguments in its behalf, to its proper appreciation, are the late Dr. Pope, of St. Louis, Dr. Lyman, of Boston, Dr. Atlee, the late Dr. Miller, of Louisville, Ky., Dr. Peaslee, and Drs. Hamilton and Reeve, of Ohio. In regard to the diagnosis of cystic diseases of the ovary, no more important addition has been made than the examination with the microscope of the contained fluid by Dr. Drysdale.[1] Dr. Atlee has established important rules of diagnosis from the coagulability of the fluids obtained from uterine or ovarian cysts, or from the abdominal cavity.[2]

[1] DEAR SIR: Since reading the paper at St. Louis, in 1873, "On the Granular Cell found in Ovarian Fluid," I have continued the investigation of these and other dropsical fluids, and have now examined over a thousand specimens of them. These examinations enable me to emphasize the opinion which I then expressed, that the ovarian granular cell is pathognomonic of cystic disease of the ovary. Yours, very truly, T. M. DRYSDALE.

[2] (1) Fluids, drawn from the peritoneal cavity, or from ovarian or broad ligament cysts, do not coagulate on mere exposure to air. (2) Fluids, drawn from non-inflammatory accumulations in the peritoneal cavity, will coagulate more or less under the influence of heat and nitric acid. (3) Fluids, drawn from inflammatory accumulations, will coagulate by heat and nitric acid; and will also, by standing, produce a fibrinoid deposit in small quantities without heat and nitric acid. (4) Fluids of ovarian cysts proper, will coagulate to a greater or less extent by heat and nitric acid. Certain fluids, however, may collect in the parenchymatous structure of an ovarian tumor, which will neither coagulate by heat or nitric acid, nor on mere exposure to air. (5) Fluids of cysts of the broad ligament will not coagulate by any means. (6) Fluids, drawn from fibro-cystic tumors of the uterus, are distinguishable from all others taken from the abdominal cavity by coagulating rapidly on exposure to air, and, after standing, by separating into clot and serum. This fluid, when not stained with red blood, is very transparent and of a yellowish color, and is really blood, or liquor sanguinis *minus* the red corpuscles. WASHINGTON L. ATLEE.

In the operation itself the most important advance is the enucleation of the cyst according to the method of Dr. Miner, of Buffalo. This method is not of general, but of particular, application, and permits the safe removal of tumors that otherwise could not be dealt with in consequence of adhesions. Clamps, instruments used probably by only a minority of American operators, have been devised by Atlee, Storer, Dawson of New York, and Mears of Philadelphia. Peritoneal drainage after operation has been practically studied by Kimball, Atlee, Sims, and Thomas. Dr. Peaslee has shown the utility of intra-peritoneal injections in septicæmia, regarding them as more valuable than any other and all other means.

Vaginal ovariotomy originated with Dr. Thomas, in 1870. The same operation has since also been successfully performed by Dr. Davis, of Pennsylvania, Dr. Gilmore, of Alabama, and Dr. Battey, of Georgia.

Ovariocentesis Vaginalis has been greatly improved by Noeggerath, and the results he has had are remarkably favorable.

Removal of the ovaries in order to determine the menopause in certain cases where menstruation is attended with great suffering, and otherwise incurable disease, was the proposition of Dr. Battey. The operation has been performed sixteen times,[1] with three deaths, the operators being Dr. Battey, Dr. Sims, and Dr. Thomas. Its propriety is hardly established in the face of such statistics.

Did time permit, many other contributions to operative gynæcology might be alluded to, such as that of Nott,[2] extirpation of the coccyx for coccygeal neuralgia, in 1844; Schuppert's[3] operation for obliteration of the vagina, in 1858, "the first case of vulvar occlusion by elytro-episiorraphy without ulterior accidents;"[4] and Emmet's method of securing the restoration of the anal sphincter in operation for ruptured perineum, a method which has recently been successfully followed by a surgeon of Rouen.[5] So, too, we might mention the peculiarities of Dr. Bozeman's operation for vesico-vaginal fistula—his knee-chest support, his self-retaining speculum, his button sutures, his method of auto-plasty by gradual approaches,[6] and, above all, his past successes at home, his present abroad, might be mentioned. The merit of a method will be at once conceded when it has won the approval of such men as Simon, Braun, and Dolbeau.

One of the minor, but by no means insignificant advantages of the establishment of a method of cure for vesico-vaginal fistula, that must not be omitted, is that in consequence thereof the operation of vaginal lithotomy is relieved of its most serious objection—the resulting fistula. Now surgeons, following the example of Dr. Sims, in 1850, remove the calculus by vagino-vesical incision, and immediately close the opening with silver sutures. This operation is growing in favor; in this country forty-one cases have been collected by Dr. Mastin: "the operation,"[7] says Dr. Warren, "seems to have been done more frequently in this country

[1] Dr. Trenholme, of Montreal, and Dr. Peaslee, have reported cases of the operation since the delivery of this address.

[2] American Journal of the Medical Sciences, October, 1844.

than in any other." Hybord,[1] in considering the relative advantages of lithotrity, dilatation and lithotomy, observes that the latter, especially vesico-vaginal, with immediate suture, is preferable if the calculus is hard, large, or encysted.

But turning from these and many other topics, and concluding this division of the subject, we cannot refrain from a remark or two concerning the surgical development of American Gynæcology. Of course in this country, as in others, the advance has been much greater in the surgical than in the medical department of so-called uterine therapeutics. In explanation of this fact, as it is observed here, two peculiar causes have been in operation, in addition to those which are common. One of these is in the characteristics of the American mind—its tendency is to action rather than to reflection; quick and fertile in expedients, it seeks immediate results, rather than exercises the patience for recondite investigation. And again, most of those who have made themselves especially famous, and therefore have become leaders of sentiment and of action, have acquired their celebrity and influence by brilliant operations. An inspiration comes from the graves of the dead and from the deeds of the living, kindling hope and ambition, to emulate their fame, and to do their works, or even greater works. American Gynæcology has proved its power, and recorded triumphs that cannot perish. The past is secure. The future is the child of the past, and its glories may be more numerous and grander.

"Men, my brothers, men the workers, ever reaping something new;
That which they have done but earnest of the things that they shall do."

Let us hope that, as Uterine Surgery has in this country made such great progress, and accomplished so much, the future historian will record similar progress and a corresponding development of Uterine Medicine.

The first American work on Diseases of Children, entitled, "A Treatise on the Physical and Medical Management of Children," was by Dr. Dewees, and published in 1825. Up to 1842 no less than seven editions had been issued. "To Dr. Dewees we are greatly indebted," said Dr. Hodge, "simply for fixing attention on the physical management of children, independently of the high value of his directions; for, prior to this period, the profession in this country left the details almost exclusively in the hands of nurses and midwives, with all their tormenting ignorance and officiousness." Dr. John Eberle, one of the first professors in Jefferson Medical College, then a professor in the Medical College of Ohio, and finally in the Transylvania School at Lexington, Ky., where he died in 1838, was author of a Treatise on the Diseases and Physical Management of Children, which was published in 1837. A third edition appeared in 1845. Dr. Eberle was a compiler, but was always judicious in his compilations.

In 1841, the Practical Treatise on Diseases of Children of Dr. James Stewart was published. This was, according to Dr. Condie, "certainly superior, in many points of view, to those heretofore accessible to the great body of our profession in this country." The author refers to the fact that opium is of admirable benefit in many of the inflammatory complaints of children, especially after bleeding, and was much in use by the older American practitioners. The practitioner of to-day would use the

[1] Des Calcules de la Vessie chez la Femme et les Petites Filles. Paris, 1872.

opium much oftener than he would the bleeding. The year 1844 brought another Practical Treatise on Diseases of Children, the well-known volume of Dr. D. Francis Condie. The sixth edition of it was issued in 1868.

Dr. Condie was, according to Prof. Stillé, by long and extensive experience, accurate observation and diligent study, not only of English writers, but also of the Continental, and especially of the German, well qualified to prepare such a work. The volume grew with each new edition, especially in accretions from foreign sources, and one who reads it now will, without the greatest care, occasionally get lost in conflicting pathological opinions and theories. But no one can mistake the two important characteristics of the therapeutics—great caution in the use of opium, great faith in the power of mercurials. Few American physicians have equalled Condie in medical learning, and the hundreds, possibly I might say thousands, of pages of criticism he has contributed to the American Journal of the Medical Sciences, constitute an important feature of our national medical literature. He was remarkably fluent in composition, yet no one could say—

> "His talk was like a stream which runs
> With rapid course from rocks to roses."

Rocks, big, solid rocks, enough there were in his writing, but roses fared as ill at his hands, as the poppy-heads that fell before Tarquin's angry cane.

In 1848, A Practical Treatise on Diseases of Children, by Dr. J. Forsyth Meigs, was issued by Lindsay and Blakiston. This was the third of the series of manuals which this well-known firm engaged in publishing, the first being the work on Obstetrics, by Dr. Tucker, to which reference was made in a former part of this address. Meigs on Diseases of Children has been and still is held in much esteem by the American profession. It has passed to the fifth edition, and in the preparation of the two last editions Dr. Wm. Pepper has been associated with Dr. Meigs.

A Treatise on the Diseases of Infancy and Childhood, by Dr. J. Lewis Smith, was issued in 1869; the third and latest edition appeared in 1876. "Smith" is a book of fewer pages than "Meigs and Pepper," but clearly and concisely written. As a guide for the practitioner, and as a text-book for students, it hardly has a superior.

In 1849, Dr. John B. Beck, one of the first professors in the College of Physicians and Surgeons, New York, published his work on Infant Therapeutics, which Dr. Gross[1] recently pronounced "a perfect gem in its way." The late Dr. C. R. Gilman[2] states that "it was received with the greatest favor, both at home and abroad. Few medical books of its size contain an equal amount of sound learning and practical good sense."

Observations on certain of the Diseases of Young Children, by Dr. Charles D. Meigs, was issued in 1850. Here we have, in the midst of excellent and most useful instruction as to the management of several of the diseases of children, some of the author's peculiar pathological views, views which were always ingenious, and, if not always true, never failed of the semblance of truth. Here we are taught the efficacy of a woollen cap in coryza, the "right-side treatment" of cyanosis, and are brought face to face with that "endangium" which played so important a part in his theories of disease.

[1] History of American Medical Literature. [2] American Medical Biography.

In Dr. Bedford's valuable Clinical Lectures, already referred to, some of the diseases of children are treated of plainly, practically, and wisely, but there is by no means a complete course given. Indeed, in reading this volume, and finding here and there these diseases considered, while the great body of the work is occupied with diseases of women, one is reminded of a street-car or omnibus crowded with adults, and then here and there a child interposed or superposed.

Having thus briefly noticed these different volumes, we shall next refer to a few special American contributions to Pædiatrics. Among the earlier, must be placed the letters on Angina Trachealis, by Dr. Richard Bayley, of New York, 1781, to Dr. William Hunter. Dr. John W. Francis[1] speaks highly of these letters, and states, "we are justified in giving to Dr. Bayley the merit of being the first writer who understood the nature and treatment of croup." In a letter written to Dr. Fothergill by Cadwallader Colden, New York, October 1, 1753, the writer describes diphtheria and its treatment, chiefly as observed by Dr. Douglass, of Boston. In 1736, Dr. Douglass published a pamphlet[2] entitled, The Practical History of a new Epidemical Eruptive Miliary Fever, with an Angina Ulcusculosa which prevailed in New England in the years 1735 and 1736. "The first full description of this affection published in this country," says Dr. J. F. Meigs, "was by Dr. Bard, and based on an epidemic which occurred in 1771. The views advanced in his paper have been universally recognized, even to the present day, as most clear and just." Dr. Bard's account of the disease has been recently very favorably referred to and quoted by Loraine & Lépine.[3]

Shall we mention one of the first applications of electricity as a therapeutic agent, in this country; its successful use in 1752 by the illustrious Franklin in a case of convulsions, in a patient of Dr. Cadwallader Evans, of Philadelphia, a girl of fourteen, who had been afflicted for ten years?

In regard to the treatment of croup, four important therapeutic agents have been introduced by American physicians. The mercurial treatment is attributed to Dr. George Monroe, of Delaware, who graduated at the University of Edinburgh in 1786. Dr. Hubbard, of Maine, is to be credited with first using and advising the yellow sulphate of mercury, a remedy which has received from Dr. Fordyce Barker, after using it twenty-eight years, the highest possible praise. The late Dr. Charles D. Meigs was the first to advise the common alum as an emetic, while more recently the treatment by cold has been ably advocated by Dr. Jacobi.

The most valuable contributions to the subject of umbilical hemorrhage have been by three American physicians, Drs. Minot, Stephen Smith, and J. Foster Jenkins.

The subjects of masturbation and hysteria in young children have been elaborately presented by Jacobi, whose many and valuable contributions to Pædiatrics are so well known to the profession, not only at home but abroad

Dr. R. W. Taylor[4] has produced a monograph upon Syphilitic Lesions of the Osseous System in Infants and Young Children, which has attracted much attention, both in this country and in Europe.

Dr. Busey[5] has given a faithful study of the action of certain drugs in

[1] Anniversary Discourse before the New York Academy of Medicine, 1847.
[2] An abstract of this paper will be found in the Medical Recorder, Philadelphia, 1825.
[3] Nouveau Dictionnaire de Médecine et de Chirurgie Pratiques, vol. xi.
[4] American Journal of Obstetrics.
[5] Columbia Hospital Report.

bronchitis. And thus, name after name might be mentioned, paper after paper referred to, showing how active the American profession has been in the department of diseases of children. But this address has already transcended the time assigned it, and I must conclude.

Did time permit, I might mention the organization of societies devoted to the especial study of obstetrics, and of diseases of women and of children, in Louisville, Boston, New York, and Philadelphia, as at once the signs and means of advance. So too, the American Gynæcological Society, born this Centennial year, gives promise of high honor and great usefulness. The establishment of hospitals devoted to diseases of women, is another evidence of progress. The Woman's Hospital of New York, founded and built chiefly by the labors of Sims and Emmet, and which has been of such incalculable benefit to thousands of suffering women, and to the profession, has been the noble pioneer. May the day speedily come when every State shall have a similar institution!

The American Journal of Obstetrics, founded by Dr. Dawson, and conducted with such signal ability, the demand for the reprint of the Obstetrical Journal of Great Britain and Ireland, and the valuable additions made to it by American writers, are evidences of progress.

And now, in conclusion, have we brought the names of those who, in this country, have been prominent in advancing the knowledge of Obstetrics, Gynæcology, and Pædiatrics, for apotheosis in some new Olympus? Nay, rather, for inscription in our memorial window of the Temple of Medicine. There let them be written, Samuel Bard, William P. Dewees, Thomas C. James, Ephraim McDowell, Charles D. Meigs, Gunning S. Bedford, Hugh L. Hodge, D. Francis Condie, Henry Miller, Walter Channing—but I cannot repeat the long list.[1] There let them all be recorded, and there forever abide. It is done. Lo! the Orient sun of the Republic's second century is pouring its light upon them, is kindling in our hearts gratitude and joy, and evoking more than MEMNONIAN music, TE DEUMS and JUBILATES, from a multitude whom no man can number, who lived because *they* lived, who suffered and who were saved from their sufferings and from the sorrows of death by the interposition of *their* Divine Art. When that sun is sinking behind the flood of years, may its departing rays gild those names with a new glory, shining too on others still more illustrious.

[1] Is it presumptive to interpret the presence with us to-day of two eminent obstetric teachers from abroad, as a cheerful tribute to the value of American work in this department of Medicine? To those teachers, one of them the honored occupant of a chair made illustrious by the names of the Hamiltons and of Sir James Y. Simpson, and the other whose fame has gone out into all the earth, and whose imperial authority the professional world acknowledges, every American physician gives hearty thanks.

ADDRESS ON MEDICAL JURISPRUDENCE.

WITH

NOTES AND A BIBLIOGRAPHICAL APPENDIX.

BY

STANFORD E. CHAILLÉ, A.M., M.D.,

PROFESSOR OF PHYSIOLOGY AND PATHOLOGICAL ANATOMY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF LOUISIANA.

MEDICAL JURISPRUDENCE owes its power to knowledge derived from every branch of medicine, but the law determines how far this power shall be utilized in the administration of justice. Hence, the development of Medical Jurisprudence has varied in different nations with the progress of medical science, and with the extent of its application to the protection of property, reputation, and life. Efficiency in this legal application varies with the appreciation of medical knowledge by the rulers of a nation; and (since an adequate appreciation is limited to the educated few, and is not yet disseminated among the mass of any people), it results, that laws more favorable to the culture of legal medicine are to be found in nations ruled by the educated few, than in those governed by the people. The unequal development of Medical Jurisprudence in different nations finds in these facts an explanation, in large part at least, and recalls the political axiom that "arbitrary powers well executed, are the most convenient," while "delays and inconveniences in the forms of justice are the price that all free nations must pay for their liberty in more substantial matters."[1]

The papal canon-laws,[2] originating many medico-legal questions, sowed in 1620 by the hand of Zacchias,[3] a pope's physician, the first sound seed of Medical Jurisprudence in the land of Columbus, then the home of Science and the Arts.[4]

[1] Blackstone, iv. p. 350. Blackstone's "Commentaries on the Laws of England" (four books) were published a century ago, viz. 1765 to 1769, and, hence, are frequently referred to.

[2] The "Corpus Juris Canonici," a compend of the canon-laws, is dated 1580.

[3] B. 2. This and all succeeding references to "B," refer to the Bibliography, with the numbers therein.

[4] From many facts which might be cited to prove this statement, as also that the development of medical jurisprudence in different nations has varied with their culture of medical science, the following quotation is selected from p. 142 of Russell's "History and Heroes of Medicine," London, 1861: "If we survey the social and political state of Europe from the twelfth to the sixteenth century, in its relation to the development of medical art, our attention is at once arrested by Italy, which at this period was far ahead of the rest of the world. Taking the number of Universities as an index of civilization, we find that before the year 1500, there were sixteen in Italy, while in France there were but six; in Germany . . . there were eight; and in Great Britain two; making sixteen in all—the exact number which existed in Italy alone. The Italian Universities were likewise no less superior in fame than in number to those of the North." Italy maintained this superiority during, and even after, the sixteenth century.

The new-born shoot, languishing in Italy, was transplanted in German soil, where it received such culture as nourished its growth, developed its fruit, and reproduced seed to germinate in other lands. To favoring legislation from 1532[1] to the present day, the fatherland owes its pre-eminence in Medical Jurisprudence. Germany, for two centuries, has had an organization of medico-legal officials, to whom alone it intrusts the duty, both to procure the medical facts needed by the courts, and to estimate the weight due such facts from whatever source obtained; it alone requires that these experts shall be especially educated, and provides medico-legal clinics[2] for their practical instruction. In 1650, Michiaelis[3] delivered the very first lectures on Legal Medicine, and as early as 1720 professorships of the same were founded by the state. By 1725, the celebrated works of Valentini, Teichmeyer, and Albertus,[4] had supplanted that of Zacchias; and since then a medico-legal literature more abundant than in all other languages has nourished the science of Medical Jurisprudence both at home and abroad. In fine, Germany, specially excelling in the Art, has consequently excelled in the culture of the Science.

France, from 1570 to 1692, enacted laws which, like those of Germany, favored the culture of Legal Medicine; but in 1692, medico-legal offices became hereditary and venal, and Legal Medicine languished until after the French Revolution. Since 1790, no nation has surpassed France in the culture of medical science; in addition, the judges appoint medical experts, who, since 1803, must be graduates in medicine, and must have attended one course of lectures, and have passed an examination on Legal Medicine, professional chairs of which were established by the state in 1794.[5] However, French authorities denounce their didactic instruction as insufficient for the education of experts, and declare the appointment of these by the judges, and the lack of skilled medico-legal officials to procure medical evidence, to be most unsatisfactory, and their whole system to be much inferior to the German. Still, France has at least a system, and meanly as this does apply the art, it has served to greatly stimulate the culture of the science, as has been notably illustrated since 1796[6] by French medico-legal literature. A critical appreciation of how much of this literature has been derived from Germany, and how much of medico-legal science without the art has been transported from Germany and France to Great Britain, and the United States, would, I fear, prove offensive to Gallic, and still more to Anglo-American, vanity.

Great Britain transmitted to this nation laws, barbarously conspicuous for the absence of provisions to apply medical knowledge to the administration of justice, and Anglo-American law continues to be, in large measure, hostile to Medical Jurisprudence. However, British laws have done something for the science, and a little for the art. For Great Britain has fostered medical education; did in 1803 found a chair of

[1] The Constitutio Criminalis of Charles V, 1532, (published in 1553) rendered it obligatory on the Courts to take the evidence of medical men in medico-legal cases.

[2] The first one established was at Vienna, about 1830; a second at Berlin, 1833; a third at Munich, 1865; and probably a fourth since 1870 at Strasbourg, where France had its only medico-legal clinic, 1840 to 1870. In France, Great Britain, and the United States, Medical Jurisprudence cannot be said to be practically taught, except as to Toxicology.

[3] University of Leipzig; Michiaelis was succeeded by Bohn.

[4] B. 29, 30, 31.

[5] Chaussier, in 1790, was the first lecturer, and Mahon, in 1795, (B. 115) the first professor. Foderé says the state enacted the first laws favorable to Legal Medicine in 1792.

[6] The date of the first French general treatise (B. 114).

Forensic Medicine in one University,[1] and now has such chairs in all its medical colleges (some of these conferring a special degree in State Medicine);[2] has by the Registration Act and other laws[3] greatly strengthened the medical profession; and has compelled its courts to accept expert evidence only from registered, and therefore educated, medical men. Still, "the crowned republic" remains destitute, as does its democratic American offspring, of popular, and hence of governmental, appreciation of the legal importance of medical knowledge, as is proved by the same lack of any system to secure the medical evidence of competent experts that characterized its laws when surgeons were barbers,[4] and when physicians were astrologers, sorcerers, and interpreters of dreams. What wonder that Germany and France began the study earlier, and have prosecuted it more successfully?

The States of this Union have, for the most part, left the culture of medical science to individual enterprise which supplies solely that which the private citizen demands—practitioners of medicine to heal the sick. The States have as yet made no demand for competent medical experts to aid the administration of justice, and have done nothing designedly for the culture of Medical Jurisprudence. What growth can this branch of State Medicine have as long as a State does not recognize even its existence? Before attempting to answer this question, it will be well—having now briefly examined the causes—to present as briefly some illustrations of the extent of the general progress of Legal Medicine.

To appreciate progress during any period, it is necessary to keep in mind the empire of the dead over the living; to recall some of the victories gained over superstition and ignorance during the preceding century, as well as during that now closing.

From 1620 to 1722, the authority of the father[5] of medico-legal science was supreme. He devoted chapters to Torture, Sorcery, Prophecy, Miracle, and Immaculate Conception. Admitting one hundred and fifty births at a labor, he skeptically doubted the three hundred and sixty-five brought forth by the prolific Countess of Henneberg! During this period doctors gravely discussed whether a woman could be got with child by the devil, or by a dream; and French judges legitimized an infant in a case where the husband had been separated four years from the mother, on the ground that the child owed its paternity to a dream. Doctors taught that grossly deformed infants had a bestial parentage; judges, even in 1769, declared that they had "no inheritable blood" for

[1] University of Edinburgh: Dr. Duncan, Sr., in 1801, was the first English speaking lecturer on Forensic Medicine, and his son the first professor, in 1803. In this same University (chartered in 1582) was established, in 1726, the first English-speaking Medical Faculty, which conferred degrees on less than 300 graduates from 1726 to 1776. From 1705 to 1726 twenty-one medical degrees, which would now be deemed irregular, perhaps honorary, were conferred. Institutions for medical education were established in Italy, Germany, and France, long prior to 1705 or 1726.

[2] Each of the twenty-three medical colleges reported in England and Scotland in 1875, had a regular teacher devoted to Forensic Medicine; and some of these, at least those at Cambridge, Oxford, Edinburgh, and Dublin, confer a special degree in State Medicine on those applicants only who have already graduated in medicine, and have thereafter satisfactorily pursued this special study.

[3] The Registration Act was passed in 1858. "Glenn's Manual of the Laws affecting Medical Men," London, 1871, gives a list of 36 such laws from 1800 to 1870, and of these 25 from 1850 to 1870.

[4] Surgeons were barbers in England until 1745.

[5] B. 2.

a "reason too obvious and too shocking to bear a minute discussion,"[1] and the priest, encouraging doctor and judge, cried "Si tu es homo, te baptizo."

Until 1726 (Albertus), it was taught that, in presence of the murderer, his victim's wounds did "open their congeal'd mouths and bleed afresh," and courts accepted the testimony of medical experts to this miraculous bleeding of the corpse.[2] The effect upon a suspected homicide of touching the dead body of his supposed victim, continued to be a legal expedient within the nineteenth century.[3]

Unearthed bones served to convict men of murder, and yet these accusing bones, since not even human, were not those of missing men. A cranial foramen devised by nature, yet perverted by ignorance into an assassinating awl-hole, would have hung Thomas Bowman, but for accident.

Superstition, denouncing medico-legal autopsies even more fiercely than it now does cremation, did not permit these to become frequent until about 1750; and the work of the father of morbid anatomy,[4] a foundation stone of Legal Medicine, was not published until 1761. By superstition, and by ignorance of normal and morbid anatomy, of the causes of sudden death, of diagnostics, and of chemistry, Legal Medicine was powerless, when compared with its present state. So great was its helplessness, that a horrible atmosphere of suspicion encompassed the fear of death by poison. On those even suspected, the grossest legal abuses were everywhere inflicted; while those convicted were long boiled alive by English law, and burned (as late as 1780) by the French "Chambre Ardente,"[5] which was not abolished until 1791.

The highest medico-legal authorities[6] taught belief in ghosts, witches, and possession by the devil; and united with the clergy until 1752 in denouncing all disbelievers thereof as heretics and atheists. They found demoniacs for the jailor and the stake, where we find patients for the doctor and the asylum. The distinguished medico-legist, Hoffman, commended to the barbarity of the law those who "vomited nails, hair, wax, glass, or leather," as indisputable witches.[7] The "great and good" Lord Chief Justice Hale, prompted by the medico-legal testimony of the learned physician Sir Thos. Browne,[8] illuminated the stake with witches—exemplifying in 1664 the practice of Anglo-American witch-laws till 1727, laws not repealed until 1736.[9] Thus did the legal medicine of our ancestors, only five generations removed, persecute, drown, and burn thousands of the insane, as "fire-brands of hell," who were "moved and seduced by instigation of the devil."

[1] Blackstone, II. pp. 246-7.

[2] See plea of the great scholar and lawyer, Sir George McKenzie, in the "State Trial," 1688, of Sir Philip Stansfield, executed for the murder of his father.

[3] The latest American case was in New York in 1824. (See B. 349, I. p. 807.)

[4] Morgagni, B. 18.

[5] Instituted at the close of 17th century as a special remedy for poisoning, which had become a very frequent crime in Paris.

[6] Paré, Zacchias, Hoffman, Storck, Boerner, &c., (B. 100, 2, 34, 39).

[7] "De diaboli potentiâ in corpora." Hoffman died in 1742.

[8] Author of "Religio Medici," and also of "Pseudoxia Epidemica," or Vulgar Errors.

[9] The "witch-mania" originated with a papal edict in 1484. The last judicial executions for witchcraft were in England, in 1716; Scotland, 1722; Würzburg (Germany), 1749; Glarus (Switzerland), 1780. The witch-mania prevailed in New England, 1692 to 1727. Although the witch-laws were repealed in Great Britain in 1736, yet as late as 1760 supposed witches were murdered by mobs, and there were "witch-doctors" in 1838. In France there was a legal trial for witchcraft as late as 1818.

These few examples must suffice to recall the parentage of the Medical Jurisprudence of our century, and the facts that, with the impotence of science to aid the law, it adopted miracles as explanations, suspicion as proof, confession as evidence of guilt, and "torture as the chief witness,"[1] summoning the medical expert to sustain the accused until the rack forced confession.[2]

During the hundred years now closing, the progress of medicine has been greater than in all preceding time. To detail the means acquired to aid the law, would require the record of every medical discovery: for what one of these may not contribute to the administration of justice? This occasion precludes more than bare suggestions illustrative of the general progress of medico-legal science.

(1) Innumerable precious facts have been contributed by every branch of Anatomy, and especially by Pathological Anatomy. The study of putrefaction, fractures, burns, scars, marks, stains—in fine of every change and injury to be found on the living or dead body—has given the skilled expert a power (miraculous to the ignorant) to identify the body, to distinguish real from apparent death, to approximate the date of death, to decide whether it be due to morbid, accidental, or criminal causes, and often to point unerringly to the criminal.[3] So great is this power that medico-legal autopsies have become indispensable to justice; and, since 1837,[4] the Microscope, strengthening notably Anatomy as also Toxicology, has repeatedly released the innocent from the jailor's clutch, and delivered the culprit to the hangman.

(2) Diagnostics, aided by stethoscope, thermometer, and many other instruments[5] invented or newly applied since 1776, have stripped the malingerer of power to feign disease, become the corner-stone of Life Insurance, and aided the law in many other particulars.

[1] Montesquieu, 1748.

[2] It is true that in our motherland, England, torture was abolished in 1640 (a century and a half earlier than in continental Europe); but, to such extent did suspicion replace proof, and the single penalty of death overtake every species and grade of crime, that the law had much less need than now of medical experts. Prisoners accused of a capital crime were not permitted any witnesses until 1702 (Blackstone, IV, p. 360); an accusation of infanticide sufficed for conviction, unless there was one eye-witness to the birth, until 1802 (B. 153, p. 309); and "prisoners were first allowed the assistance of counsel" about 1830 ("Science of Law" by S. Amos, p. 312). Even in 1769 there was "a dreadful list of 160 capital offences," and, not content with this liberal supply of the halter, English laws provided for criminals horrible mutilations, as branding, castration, slitting the nostrils, cropping the ears, and cutting off the hand, with a medical expert to sear the stump; death by exposure and starvation ("Peine fort et dure"), till 1772, by beheading, by drawing and quartering, and by burning alive; and brutal persecution of widow and orphan by corruption of blood and confiscation. Yet Blackstone asserts (1769), with evident pride, that this "disgusting catalogue" when compared with the criminal codes of other European nations did "honor to the English law." It is calculated to soften impatient indignation to remember that "it cannot be justly regarded as a fault in [legislators] courts or juries not to be in advance of the age in which they live"; and it is encouraging to recall that many of these barbarous laws were repealed because courts and juries did get so much in advance of them, that they could not be executed.

[3] Among errors credited by the profession and corrected within the 19th century may be mentioned here: the beliefs that the human hair could grow after death; that the wind of a canon-ball could destroy life; and that violent and fatal injuries, which at times do fail to leave any visible signs externally, might also fail to present any lesions internally.

[4] Schwann and Schleiden.

[5] Spirometer, Pneumatometer, Galvanic and Electric Batteries, Ophthalmoscope, Laryngoscope, Endoscope, Spectroscope, Sphygmograph, Cardiograph, Dynamometer, Æsthesiometer, etc.

(3) Obstetrics, until 1750 in the hands of ignorant midwives,[1] consequently remained a special nursery of mystery and credulity. During the present century, Obstetrical Jurisprudence has rescued from ignorant superstition monsters, retarded births, superfœtation, and hermaphrodism; has discovered new signs of pregnancy, and the significance of uterine moles[2] and hydatids; has appreciated the evidences of impotence, sterility, and "live-birth," and has discarded the hydrostatic test[3] as conclusive proof of the latter. In vindication of chastity, the signs of virginity[4] have been duly estimated, false have been distinguished from true corpora lutea,[5] and it has been proved that sexual connection "without consent" may be fruitful. Finally, the "jury of matrons" has been slowly despoiled of its authority to decide a question of pregnancy. It is mortifying to record that, in criminal cases, the laws of some of our States continue to regard "quickening" as proof of the very dawn of life; and yet add to this barbarism the inconsistency of admitting, in civil cases, the vitality of the embryo from the date of conception. More than a century ago, medico-legists,[6] abandoning a belief long universal, taught that life began months prior to, and was as sacred before as after, maternal sensation; but, to the encouragement of fœticide, this ancestral superstition[7] still prevails among a free people, and lingers in their laws.

(4) Chemistry, since 1789, when Lavoisier gave it a firm foundation, has enriched every science, bestowing such services on State Medicine as to necessitate the distinct department of Legal Chemistry. Two of many services may be mentioned: the murderer has been deprived of one refuge, which even professional credulity supplied—Spontaneous Combustion[8]—a mode of death yet to be witnessed by a skilled expert; but this interesting service is insignificant when compared with that rendered toxicology. Though poisons have become much more procurable and numerous, yet the skill of the medical chemist has so increased, that criminal poisoning has become, largely through this power, one of the most certainly detected, relatively infrequent, and least dreaded modes of death.

(5) By the knowledge acquired of the nervous system, medical science has influenced society and law to an extent difficult to over-estimate.

[1] A man-midwife was first employed with the greatest secrecy, in 1663. In England, men-midwives did not secure respectable professional position until 1783. Prof. T. G. Thomas writes that in the United States the subject of obstetrics has "been recognized as one of paramount importance and dignity" since 1767.

[2] The French Parliament decided in 1781 that virgins and nuns discharged moles (*i. e.* "blighted ova") without having had sexual connection. (B. 114, 2d Ed. I. p. 477.)

[3] The hydrostatic test was first practically used in legal medicine by Jan Schreyer in 1682, and was long accepted as conclusive proof of live-birth.

[4] Buffon, as also Foderé (B. 114, in the 1st Ed. of 1796, not in the 2d Ed. of 1813), Mahon (B. 115) and many others taught that there was no such thing as the Hymen.

[5] In the trial of Chas. Angus (Lancaster, England), for the murder of Miss Burns, in 1808, all the medical witnesses testified (to her dishonor) that all corpora lutea without distinction proved previous conception.

[6] Faselius, 1767; Haller, 1782; Farr, 1788, etc.

[7] "Absurd ecclesiastical canons handed this error down from one criminal code to another." B. 349, II. pp. 9 and 1076; Foderé, etc.

[8] This debt is due chiefly to Liebig and Bischoff (Case of the Countess of Goerlitz, 1850). Casper wrote: "It is afflicting to be obliged in a serious scientific work in 1861 to still speak of the fable, spontaneous combustion." A human body reduced in a few moments to a cup of ashes! To the credulous in this matter, one is prompted to recall Velpeau's attitude in reference to the "vagitus uterinus," or capacity of the fœtus (inclosed in its membranes) to cry in utero—a belief long firmly attested and universally credited. Said Velpeau: "Since learned and credible men have heard it, I will believe it; but I should not believe it if I had heard it myself!"

In 1774, England enacted the first law evincing one touch of pity for the insane; in 1792, Pinel[1] adopted the first humane treatment of their disease. Since then, civilization has been slowly taught that those upon whom our grandfathers inflicted "the pains of Hell" in order to thus drive the devil out of bodies "accursed by God," are the most pitiably diseased of all our fellow creatures, and we are enabled to point with pride to the palatial asylums with which our laws have replaced the garrets, cellars, stables, and dungeons, where starved and tortured insanity once writhed in filth and chains.[2] The history of the Medical Jurisprudence of Insanity is eloquent with the increasing number and efficiency of the laws designed to protect both society and the sufferer; and with assurances of the extension of these laws from insanity to habitual intemperance.

Is it too much to claim that the progress of Psychological Medicine has strengthened the conviction that not only mental disease, but also hereditary organization, defective education, and circumstances for which society is more accountable than any of its units, do modify criminal responsibility in *fact*, and therefore should do so in *law?* Has not this special knowledge broadened man's charity, encouraged society's efforts to redeem its outcasts, and influenced the law's amelioration of its criminal code? Is it not forcing to the front that most important social question, the problem of heredity; thus disclosing an immeasurable field for the medical research and legislative labor of our descendants? In fine, is it not true that science, stripping nature of providential caprice and disheartening chance, divinely adorning her with eternal order and omnipotent law, has gradually established that the diseases and deformities of the mind are as much as those of the body subject to nature's laws; and that the lunatic, the drunkard, the criminal, the sage, and the fool are not the products of chance, but of laws as comprehensible, though not yet as well comprehended, as those governing that thunderbolt which, once in the hand of Jove, now traverses even the depths of the sea at man's command?

The part this nation has taken in the general progress of Medical Jurisprudence must now be considered, and to test our progress five inquiries will be instituted.

I. *What have our Laws done to apply medical knowledge to the Administration of Justice?*—In the United States there are probably forty-five thousand medico-legal autopsies made annually. The service of a skilled expert at these "coroner's inquests," which have exceptional opportunity and power to detect crime, is of inestimable importance; the opportunities there presented, if once lost, can never be regained. Further, our courts have annually from twenty-five hundred to treble this number of criminal trials necessitating medical testimony; and of these a large part originate from the coroner's inquests. If to these criminal be added all the medico-legal civil trials, it would be found, I doubt not, that our courts require medical evidence in not less than twenty thousand cases annually.[3] Whatever the number may be, it would indicate inade-

[1] B. 129.

[2] In New England, say "Wharton and Stillé," the insane were sold out to the lowest bidder, who starved them, and when violent chained them in stables.

[3] I have sought in vain for full and reliable statistics to illustrate numerically the importance of legal medicine. The numbers given are only approximative estimates based partly on some meagre British statistics cited by Guy and by Taylor, and partly on the

quately the number of citizens whose welfare is involved, and the extent to which society is interested in the efficient application of medical knowledge to the administration of justice.

Now, what are the methods which Anglo-American law adopts to secure in practice that "best attainable evidence" which in theory it demands? It entrusts medico-legal autopsies, which require special medical and some legal knowledge, to those having neither the one nor the other, except by accident; for, these coroners (whose inexperience our law insures by constant "rotation in office") owe their position wholly to political popularity, a qualification which a competent expert is most unlikely to possess. Are these unqualified officials supplied with efficient aid? If so, again by accident, since the law leaves it to chance, or the coroner, or to his still less qualified jury, to provide a medical expert; and, as is usual, accident and ignorance provide inexperience and incompetence. Could ingenuity devise for medico-legal autopsies any methods more inefficient than these, which Anglo-American laws, framed before the birth of Medical Jurisprudence, have barbarously perpetuated?[1]

On this Pelion of inefficiency our legislative giants have piled an Ossa of absurdity; for, besides these fatal defects in the primary legal proceedings, Anglo-American law, in order to secure "the best attainable evidence" for its courts, where poverty and dishonor as well as the halter are administered to the free citizen, clings to a method as sadly ludicrous as it is antiquated. To plaintiff and defendant the law gives full licensé to summon such medical witnesses as each has already found reason to

following facts as to New Orleans, La., for the year 1875. The total number of coroner's views and inquests was 1026; of these there were 268 inquests, and out of these grew 47 trials. Giving New Orleans 210,000 and the United States 40,000,000 population, the New Orleans statistics would indicate for the United States annually 8952 medico-legal criminal trials, growing out of 51,047 medico-legal autopsies, or coroner's inquests.

[1] Convincing reasons could be given in proof that the duties of coroners are discharged even worse in the United States than in England. The following facts indicate how the Anglo-American method works in the latter country. An Englishman writes (1876): "The coroner is elected for life by the rate-payers of his district [a superiority over the American method], and he is paid a good salary out of the county rates. In most cases he is a medical man who has studied the arts of popularity with more success than those of medicine, or he is a small country attorney who has failed in the higher paths of his profession." Dr. Wm. Farr officially reported as to England in 1868: When all the verdicts of coroners "for the first time came under review [another great superiority over the American lack of any such system], they were not at all creditable to the intelligence of the country. They conveyed the least possible information in the vaguest possible words." Prof. A. S. Taylor wrote in 1873: "The coroner's inquest affords no certainty for the detection of crime. It, in some instances, tends to screen a criminal." "In the course of thirty years' practice, at least fifteen cases of the exhumation of dead bodies were referred to me. On some of these inquests had been held, but no inspections were made. Verdicts of death from cholera or natural causes had been returned, and at intervals of from one to twenty-two months the bodies have been disinterred, and it was then proved that the deceased persons had died from poison." (See B. 358, I. p. 12.) The British Medical Journal (Jan. 1876) reports a glaring case of poisoning, undetected by the incompetent coroner. National attention was recently attracted to the same monstrous evil in the inquest of a Mr. Bravo. An English writer asserts that "almost every day, from all parts of England tales come up of the inadequacy and absurdity of the institution. Notice has been given to-day [May 23d, 1876] in the House of Commons, by an independent member on the ministerial side, that he will call attention to the office of coroner at an early day." Other facts indicate that England recognizes this evil better than does the United States, and therefore will probably correct it sooner. July, 1876, it was reported that "the practice of electing coroners has been condemned in the House of Commons by a unanimous vote. A bill for the reform of the office of coroner is soon to be brought in." See also B. 259, 274, and 330.

believe entertain opinions the most contradictory.[1] Who are these partisan witnesses thus summoned by the law to apply the power of medical knowledge to the administration of justice? Surely these legal representatives of science must be competent experts? No.—Well, experienced and educated physicians of repute? No.—Then, of course graduates, at least some fledgling hatched in nine months, and fully feathered with the plumes of every branch of medicine, Medical Jurisprudence included? No, not indispensable, since "as a general rule" it has been adjudged that any practitioner of medicine (that is, any man who dubs himself Doctor) has sufficient knowledge of medical science to furnish justice with its "best attainable evidence."[2] "O, [this] offence is rank, it smells to Heaven!"

Common sense would presume that laws, so prodigal to ignorance and pretension, would provide means to test the value of scientific opinions by eliciting the facts upon which, if valid, they must be founded. Not so; since these opinions are replies to questions, which often by their very structure comically prove entire ignorance of the facts involved; for they are propounded by lawyers to whom these facts are unknown. Finally, it would be presumed that the decision as to the weight due such opinions would be left to a judge or jury specially chosen. No, even this last poor boon is denied by the law!

With the power of medical science thus crippled at the coroner's inquest, then prostituted by the partisan opinions of incompetent experts, then perverted by advocates, and at last when emasculated of all vigor submitted for decision to those unable to estimate its weight; what wonder that such gross misapplication of medical knowledge brings upon it that public contempt which belongs justly to methods so monstrous, and to which true medical knowledge is a helpless, pitiable, and disgusted victim!

But these legal defects, so paralyzing to the past, so discouraging to

[1] Reference is often made to the well-known facts that the sound expert-evidence of the illustrious John Hunter was in 1781 overborne by the evidence of three ignoramuses, and that the testimony of the famous Denman was in 1806 set aside by the Court in favor of one male and two female quacks. The same system is continued, and therefore the same evils persist. Prof. A. S. Taylor reports now, as to England, that a good search and good pay can always find, in abundance, the witnesses needed on either side of any medico-legal issue. This is certainly true as to the United States. Some facts may be cited in illustration. I have personal experience in a suit (unsoundness of a slave) in which the medical experts were selected by one side *because of their well-known ignorance* of the special knowledge (auscultation) which the issue involved; and the judge decided that the whole medical testimony must be set aside, because the negative evidence of the incompetent sufficed to counterbalance the very positive affirmative testimony of the competent experts. Death, with a post-mortem examination, soon after the decision, conclusively proved that the ignoramuses deserved no consideration in justice, though they did receive equiponderant consideration in law. Whenever a notorious trial attracts public attention, the results of our defective laws become disgracefully apparent, as has been illustrated in recent years by the Steinecke-Schoeppe (1868), the Wharton-Ketchum (1872), and the Stokes-Fisk (1874) trials (B. 363, 344, 370). If the medico-legal proceedings are so discreditable in cases like these, exciting great public interest and engaging the best legal and medical talent, what probably are they in ordinary trials lacking these advantages?

[2] The text will be found fully sustained by reference to B. 317, pp. 131–2, B. 349, I. pp. 283–5, and B. 363, p. 406. However, Elwell (B. 330, p. 589) refers to eight decisions to the effect that "special knowledge must be fully established before a witness can be examined as an expert;" but had he stated by what slight proofs, and by what incompetent judges, this "special knowledge must be fully established," the apparent discrepancy would have practically disappeared. An eminent lawyer assures me that in the courts of my native State (Mississippi) the competency of a medical expert rests solely on his own oath; and that, when his own interests and reputation prompt such an oath!

the future of Anglo-American Medical Jurisprudence, are not the only disadvantages against which this nation has had to contend. It inherited from Great Britain not even a page of the literature, in fact nothing of Medical Jurisprudence except laws hostile to it. So destitute was it of those indispensable promoters of science, well endowed institutions, with libraries, laboratories, and museums; so exhausted by the war for independence; so closely occupied by the pressing demands of daily life; and so profitably absorbed by glorious efforts to present to civilization a savage continent, that every science seems to have required half our century to secure the conditions necessary to fairly begin its culture.[1] Another potent, yet ill-appreciated friend to science, pressure of population, now wanting in many, was long wanting in every State. Finally, while a European nation requires but one legislative body to reform its laws, our political system now necessitates the action of thirty-eight State-legislatures to embrace the entire nation.

Just consideration of all these impediments should incline other nations not to condemn, if we have done little for Medical Jurisprudence, but rather to wonder that we have done anything at all; and to congratulate us that, so great has been the diffusion of knowledge, so ardent the love of justice, we have in the main kept pace with, and in some particulars have even outstripped, our mother-land. Fairly we can claim no more; reasonably no more should be expected.

II. *What have our Medical Colleges done to cultivate and to disseminate a knowledge of Medical Jurisprudence?*—The first chair of Medical Jurisprudence was established by the "College of Physicians and Surgeons" of New York City, and filled by Prof. Stringham,[2] in 1813. In 1815 two other Colleges[3] had chairs devoted to the usual branches with Medical Jurisprudence attached to some one of these. In 1825 there were about twenty-two medical colleges; of these only one had a full chair, and only five others had even the fraction of a chair devoted to the subject.[4] At present (1875–6) there are sixty-four regular medical colleges (four of these for women). A report[5] as to forty-six of

[1] To illustrate this as to medicine, and also the practical difficulty encountered by the courts in securing, under our laws, the evidence of competent experts, the following facts are stated: Prof. S. D. Gross reports that in 1776 the United States had about 3000 practising physicians, of whom the great majority had never received a medical education, and those who had, were educated abroad. Prof. Austin Flint, Sr., reports that in 1776 our two medical colleges (one founded in Philadelphia in 1768, the other in New York City in 1770) had not graduated even fifty doctors of medicine, and that up to 1800 the five colleges then existing had graduated only about two hundred. Thacher's "History of Medical Science in the United States" reports that it was computed that in 1826 the United States had 10,000 "very easily graduated" doctors of medicine, and more than 15,000 practitioners without diplomas. Prof. John B. Beck wrote that, "at no period in the history of this country, it may safely be asserted, has empiricism flourished to the same fearful extent as at the present time [1845], notwithstanding our boasted improvements in other respects." In 1870, the United States had 62,383 practitioners of medicine; of these there were perhaps 47,000 "very easily graduated" doctors, and at least 15,000 quacks outside of professional ranks.

[2] Dr. Stringham was also the first lecturer on Medical Jurisprudence in the United States, viz., in New York City in 1804.

[3] In 1815, "The College of Physicians and Surgeons of the Western District of New York" appointed Dr. T. R. Beck "Professor of the Institutes of Medicine, and Lecturer on Medical Jurisprudence;" and the Medical Department of Harvard University (Cambridge, Mass.) appointed Dr. Walter Channing "Professor of Midwifery and of Medical Jurisprudence."

[4] See "Thacher's History of Medical Science in the United States, 1828."

[5] Due to the courtesy of (my colleague on this occasion) Prof. N. S. Davis, M.D., of Chicago, Ill. The forty-six graduate more than nine-tenths of all our annual graduates. The twenty-five graduate fully one-half of the whole number.

the most noted, shows that twenty-one do not profess to teach the subject; of the remaining twenty-five, only fourteen (and these not the best known and attended) have professorships devoted exclusively to Medical Jurisprudence, and, by five of these fourteen, students are taught to become *medical* experts by *lawyers*;[1] while the other eleven have Medical Jurisprudence "tacked on as a caudal appendage" to some one of the usual branches. In fine, only about one-half of even our best colleges profess to pay any special attention to the subject; and many facts could be cited to prove that the true significance of the whole matter, from 1813 to the present day, is correctly represented by the following quotations from one of the most prominent of our living medico-legists:—[2]

"There are very few of the medical colleges in which it is taught, and still fewer in which it takes rank as a distinct and independent branch along with the other departments. Usually when it professedly receives any attention at all, it is tacked on, as a sort of appendix, to some other branch with which it has no natural affinity whatever, as, *e.g.*, Obstetrics or Materia Medica. This is of course done to make a show on the programme, while the subject itself is not taught systematically to the student, if taught at all." "I very much doubt whether Medical Jurisprudence is ever made a qualification for graduation, even in those colleges where it is professedly taught as one of the regular branches."[3]

From these facts it is manifest that, since 1813, our colleges (the offspring of the enterprise of individuals, and not of the State) have made ineffectual efforts to cultivate that special knowledge which, while highly beneficial to the State, would not benefit the individual members of our profession any more directly than any other citizens. In fact, the States through these citizens have failed to provide honorable and profitable employment for medico-legal experts, and, therefore, the profession has not furnished them; and, however enlightened the colleges, however praiseworthy their efforts, they will continue to contend in vain against the obstinate "demand and supply law" of political economy.

The profession recognizes the absurdity of the popular and legal presumption that every practitioner is a medical expert; but the profession does not yet recognize sufficiently that even the most skilful healers of disease are neither necessarily nor generally medico-legists; and that the experience of other nations has fully proved that merely didactic lectures can never render medical graduates competent experts. Were this feasible, any such ideal education is now impracticable; for who will deny (1) that our two short courses of lectures are insufficient for proper instruction even in the fundamental facts indispensable to the education of practitioners of medicine; (2) that the fundamental facts for the practitioner are the same as for the medical expert; and (3) that society remunerates the one, while the State finds no use for the other? Finally, there is reason to fear that, until the State demands medical experts, the colleges, dependent on the student and not on the State for their existence, will be forced by these practical students to realize continually the

[1] Casper insists, with good reason, that the medico-legist should remain a physician; and become neither a lawyer, jurisconsult, nor judge, but simply an expert witness, who does need from the law thorough instruction in the "rules of evidence."

[2] John J. Reese, M.D., Professor of Medical Jurisprudence in the University of Pennsylvania. (See B. 247 and 362.)

[3] Some only of our Law Schools have professorships of Medical Jurisprudence; and there is good reason to believe that the general facts as to the Medical are fully applicable to the Law Schools, as far as instruction in Legal Medicine is concerned.

force of the homely adage, "you may take a horse to the water, but you cannot force him to drink."

III. *What new Facts have Americans added, by original research, to the common stock of Medico-legal Science?*—Restricting the list to researches designedly and specially medico-legal, it must be borne in mind that the sum total of these in all nations has not been very large, and that few should be expected in this country for reasons already stated. Prof. John C. Dalton (though to some extent anticipated by Coste (1849) whose researches were unknown to Dalton) was the first (1851) to make a rigid comparison between the corpus luteum of menstruation and that of pregnancy; and to distinctly indicate the differences which, during a certain period, enable the expert to determine from an inspection of the ovaries whether pregnancy has or has not existed.[1] Dr. Joseph G. Richardson announced in 1869 the important medico-legal discovery that, by the proper application of high powers of the microscope, human blood-corpuscles could with certainty be discriminated from those of certain animals;[2] thereby enabling the expert to refute such statements as criminals have often offered to explain the presence of condemnatory stains of blood. Though the justice of this claim has been questioned, yet some of the highest authorities emphatically sustain it; and this discovery has been usefully applied in several criminal trials.[3] Dr. Richardson deserves the additional credit of having called attention in 1875[4] to a simple method of so treating a blood-stain, of even microscopic size, that it can be successfully examined by the spectroscope and guaiacum test,[5] as well as by the microscope.

Researches by which error is exposed, or truth more firmly established, are often as important to science as those which discover new facts. Among such researches may be mentioned those of John B. Beck, on Ploucquet's[6] and on the hydrostatic test,[7] in 1817 and subsequently; of Horner, on the mucous membranes of the stomach and intestines, in 1827; of Gross, on strangling, in 1833; of Wetherill, on adipocere,[8] in 1855; and of Fleming, on blood-stains, in 1859.[9]

Contributions by my countrymen to the progress of Medical Jurispru-

[1] See B. 257; also, Coste's second livraison, "Histoire du Développement," 1849; and the adoption of Coste's views in Longet's "Traité de Physiologie," II. p. 88, 1850.

[2] "An objective $\frac{1}{25}$ to $\frac{1}{50}$ inch distinguishes human blood-corpuscles in stains (but not in dried masses of blood) from those of the ox, pig, sheep, cat, horse, deer, and goat." (See B. 320, 373, 374, 376, 377.)

[3] Since the delivery of this address, eminent microscopists have made on the preceding periods two criticisms. First, that the word "discovery" is misused—since it has long been known that the blood-corpuscles of the "certain animals" are much smaller than those of man, as also that high powers render this difference in size more apparent. Second, that the words "with certainty" demand a modifying explanation, since able observers declare that cases do occur wherein human corpuscles in dried stains shrink, so as to be as small as those of the "certain animals": hence, that the expert when confronted with such small corpuscles cannot swear "with certainty" whether these be human; but if the specimen of corpuscles approximate those of man in size, then the expert can swear "with certainty" that they are not those of any one of the "certain animals," inasmuch as corpuscles in dried stains do shrink, but do not enlarge. The issue thus raised is as to the amount of shrinkage of human red blood-corpuscles in dried stains; Dr. Richardson asserts that this does not exceed ten per cent.; while others assert that this may be thirty per cent., the corpuscle shrinking in size to $\frac{1}{4300}$, or even to $\frac{1}{5000}$ inch.

dence during a century, present a field for investigation so extensive, that some of these contributions may have escaped my search, or may have been inadequately appreciated. To rectify, at least in some measure, any such defects, I present, with this address, a Bibliography of American Medical Jurisprudence, to which attention is invited. The next inquiry is:—

IV. *What culture of Medico-legal Science is evinced by our Literature?*

1. GENERAL TREATISES.—The embryonic stage of medico-legal literature in our mother-tongue is attested by the following "footprints on the sands of time." Farr's "Elements of Medical Jurisprudence,"[1] an abridged translation of Faselius, was the first general treatise in the English language, and the only one from 1788 to 1815, when another worse little duodecimo was added by Bartley.[2] In 1816 Male contributed an insignificant "Epitome of Forensic Medicine,"[3] borrowed from Plenck,[4] and in 1821 John Gordon Smith, M.D., published a small book, which was the first original and meritorious treatise in our language.[5]

In 1823 appeared, in two large octavo volumes, the American, Theodric Romeyn Beck's "Elements of Medical Jurisprudence,"[6] which, in spite of the merit of Smith's book, and of the greater merit of Paris's and Fonblanque's English treatise,[7] also published in 1823, quickly supplanted these wherever the English language was spoken. From the date of its publication, which may be deemed the origin, in fact, of Anglo-American medico-legal science, its twelve successive editions have ably kept pace with the progress of legal medicine. Filling many offices of trust and honor, a member of twenty American and seven foreign scientific societies, Prof. Beck[8] lived to witness the issue of ten editions of his treatise; of these, several were published in England, and even the prolific mother of medico-legal literature issued in 1828 a translated German edition. But to Beck's merit no testimony can be more convincing or pleasing than that gracefully given by the three eminent authors whose works eventually succeeded in largely supplanting his treatise in Great Britain. Traill, the distinguished Scotch professor and author, eulogizes it as "the best work on the general subject which has appeared in the English language;"[9] Guy "acknowledges his obligations in a special manner to Beck's learned and elaborate Elements of Medical Jurisprudence;"[10] and Taylor, than whom there is no higher living authority, testifies that he, when a student, was stimulated by Beck's work to study medical jurisprudence in 1825, when no lectures were delivered in England on the subject, and this book was the leading authority for both lawyers and physicians; and that it "will carry down" the author's "name to future years as one of the most erudite and distinguished writers on medical jurisprudence."[11]

To these testimonials from abroad may be added the eloquent eulogy of that son of America whom its medical profession delights to honor as one of its noblest representatives, and as its President on this occasion. His voice, generous to all, even loving to worth, declares that "this grand book" "was in its day the most comprehensive, able, and erudite production on the subject of which it treats in any language," and that it "constitutes a lasting monument to the genius, industry, judgment,

[9] B. 158, 2d Ed. [10] B. 161, 2d Ed. [11] B. 359.

and learning of its lamented author."[1] It is pleasing to learn from the same source that, in honoring this famous author, we are honoring the memory of a good and noble man; and this pleasure is enhanced by recalling the humble estimate which he himself accorded to his "world-renowned book." For his own statements were that his "highest ambition would be gratified" if his "collection of detached essays" should "in some tolerable degree" "prove useful." Knowing that these modest words will find a generous echo in the hearts of all noble men, to them is commended the fame of America's first and greatest medico-legal author.

In 1850, Prof. Amos Dean, a lawyer, published his brief but excellent text-book, the "Principles of Medical Jurisprudence,"[2] which has passed through three editions.

A lawyer and a physician united to produce in 1855 the voluminous and admirable general treatise, "Wharton and Stillé's Medical Jurisprudence."[3] After completion, but prior to its publication, profession and country had cause to mourn the death of the young and gifted Moreton Stillé.[4] His legal associate, deriving from other able pens indispensable medical aid, has lived to issue three editions of a work which both professions accept as one of the highest standard authorities.

Evidence of our increasing appreciation of legal medicine, as also of our obligations to foreign sources, is found in the republication, since 1819, of nine books by British authors on the general subject, viz., Cooper's collection of the earliest English tracts (1819), and the numerous valuable articles in the "Cyclopædia of Practical Medicine" (1845), which deserve mention with the general treatises of Ryan (1832), Chitty (1836), Traill (1841), Guy (1845), and Woodman and Tidy (1876); and of still greater value Taylor's "Manual," as also his "Principles and Practice of Medical Jurisprudence" (1845 to 1873).[5]

2. Treatises, Essays, etc., on Special Subjects.—Besides the excellent books of Ray, Elwell, Ordronaux, Wormley, Reese, and the New York "Medico-Legal Society," the essays and articles on special topics have been too numerous to permit full examination, or more than a partial sketch of this important branch of my subject.

Infanticide and fœticide received from Prof. John B. Beck attention in 1817;[6] and this thesis, enlarged and improved for the various editions of his brother's "great work," displays a combination of erudition, original research, sound sense, and rhetorical excellence, which render it one of the most classical essays in the medical literature of the English language. Abortion has been further illustrated by the essays of Hodge (1839, 1873), Storer (1866, 1867), Heard (1868), and others;[7] as also by numerous valuable articles in our periodical literature.[8] Apparently increasing with the pressure of population, this stain on modern civilization has become one of the most serious and hopeless problems within the province of Legal Medicine, and demands the grave consideration of every enlightened citizen.

[7] B. 236, 279, 305, 309, 314, 310, 315, 325, 341.

[8] In the "Specimen Fasciculus of a Catalogue of the National Medical Library," 1876, pp. 24–5, are reported from our medical journals thirty-nine articles on this subject, since 1825, by Americans; of these, twenty-three have been published in the last ten years.

Elwell's "Malpractice and Medical Evidence"[1] (1860, 1871) and Ordronaux's "Jurisprudence of Medicine"[2] (1869) are very valuable works—legal rather than medical—and unique, it is believed, in medico-legal literature. In connection with malpractice, Hamilton's noted essay on "Deformities after Fractures"[3] (1855) and his standard treatise on "Fractures and Dislocations" (1860–1875) deserve mention, since more than half of all trials in the United States for malpractice have originated from the results of these injuries.[4]

Supplied with domestic editions of Orfila (1819, 1826), Christison (1845), and Taylor (1848–1875), on Poisons, and with Naquet's Legal Chemistry (1876),[5] native authors have produced two meritorious works on Toxicology. Wormley's "Micro-Chemistry of Poisons"[6] (1867) has received the most flattering commendation from the highest authorities, who report this book to be the result of original researches which enrich it with the treasures most valuable to science. No more will be said, because the author is not only living but present, and no praise from me can enhance the reputation of his work. The same considerations prohibit more than reference to Reese's excellent "Manual of Toxicology"[7] (1874), which has been republished in London.

On the most important specialty, America has produced one treatise, Ray's "Medical Jurisprudence of Insanity."[8] In 1838, when first published, there were few such treatises extant,[9] and it at once assumed, and throughout an English, a Scotch, and five American editions, has deservedly maintained, the first rank in Anglo-American medical literature. An able advocate of "moral mania"—the present battle ground in the Medical Jurisprudence of Insanity—Dr. Ray does not forget, while urging a larger charity for disease, to demand ample and better legal means to protect society. Besides this treatise, essays of value have been published by Hammond (1866, 1873), Fisher (1872), and Cowperthwait (1876),[10] and numerous meritorious reports and articles have richly adorned our periodical literature.[11] It would require a volume to do justice to the medico-legal labors of the Superintendents of our Insane Asylums, and to record the evidences of progress presented solely in the "American Journal of Insanity;" while some of the most valuable essays on this and other special subjects are to be found in the publications of the New York Medico-Legal Society.[12]

There are four other works which, treating incidentally of the Medical Jurisprudence of Insanity, deserve mention: the notable "Diseases of the Mind" (1812–1835), by Benj. Rush, a father of this republic and "the father of its medical literature;" Seguin's "Idiocy" (1866); Echeverria's "Epilepsy" (1870); and Hammond's "Diseases of the Nervous System" (1871–1876).[13]

Fourteen foreign books on insanity have been republished in the United States. Five treat specially of its legal relations, viz., those by

Highmore (1822), Blandford (1871), Maudsley (1874), Sheppard (1875), and Browne (1876);[1] and nine treat of these relations incidentally, viz., those by Combe (1834), Prichard (1837), Esquirol (1845), Brierre de Boismont (1855), Bucknill and Tuke (1858), Winslow (1860, 1866), Maudsley (1867, 1871), Tuke (1873), and Wynter (1873).[2]

This incomplete sketch of our medico-legal literature attests that it has since its origin progressively increased, and that a very large proportion has been furnished during the last ten years; thus indicating a diffusion of this knowledge to an extent which encourages the hope that such appreciation of its importance is in growth as will insure its proper use.

That our progress in this literature may be properly estimated, as far at least as increase of quantity is concerned, it is indispensable to compare it with that of other nations. As concerns *general treatises*, this nation, beginning in 1823, has produced three;[3] Germany, beginning a century earlier, published at least forty before, and more than twenty since 1823;[4] France beginning in 1796 published nine before, and seven since;[5] and Great Britain, making its first creditable effort in 1821, published its second in 1823, and has issued eight since.[6] If a comparison as to *special treatises* be instituted, a like result ensues, and a search into periodical literature proves even more unfavorable. Since 1782, Germany alone has had, and now has, several journals of great merit devoted exclusively to Legal Medicine, from which flow, to the benefit of all nations, a constant stream of medico-legal knowledge. France has had, only since 1829, one of the ablest journals[7] in the world devoted to State Medicine, but not one to Medical Jurisprudence exclusively. Great Britain has no such journal, nor has this nation except in so far as represented, since 1874, by the valuable "Psychological and Medico-Legal Journal" of Prof. Hammond.

These facts tend to prove that the culture of medico-legal literature is proportionate to the use made of it by the law; and prompt the comment that, however valuable compilations may be, these and the progress of every science depend ultimately on original research, and the labor of practical workers. Germany has produced many, France several, and Great Britain one or two, practical medico-legal experts of widespread fame. This people has never had, nor is it likely to have, one, until it provides for him honorable and lucrative employment.

V. *What illustrations of medico-legal progress are to be found in the Institutions, Laws, and Judicial Decisions of our States?*—Originated by vital statistics, nourished by medical selection, protected by medical evidence, Life Insurance, the wondrous child of Medicine and Finance, encourages the hope that it will repay our science the debt it owes. Causing numerous medico-legal suits, its vast interests are deeply involved in the legal reforms indispensable to the progress of Medical Jurisprudence; for these interests are often sacrificed by the negligence of coroners,[8] the incompetence of experts, and the inefficiency of our medico-legal methods. While Life Insurance suits have most frequently grown out of intemperance and suicide, yet there would seem to be few medical issues on which they may not depend, even on whether death was due to consump-

[8] The issue has recently been raised, in reference to a case, the subject of a coroner's inquest, whether death was due to intemperance or to heart-disease. A medico-legal autopsy would have probably prevented any such issue, but this was totally neglected.

tion or to diphtheria.[1] To illustrate the progress and extent of the medico-legal interests involved, it deserves record that, in 1840, there were in the United States only three or four companies having an insignificant amount of business; that in 1874 there were seventy-seven companies insuring $2,226,000,000 upon 910,000 policies; and that the annual average number of lives insured during the past three years has exceeded 200,000.[2]

The growth of Life Insurance is one of many examples which illustrate the fact that the importance of Medical Jurisprudence has constantly increased with the progress of medicine, and the requirements of civilization. None the less, there are instances where, through legal and other causes, the bounds of Legal Medicine have been restricted.

When suicide ceased to be a felony,[3] it ceased to concern Legal Medicine, except when the suicide's life was insured; feigned diseases have under our laws little importance; and, with the abolition of imprisonment for debt, and of slavery, there disappeared from the courts many medico-legal questions. To education,[4] Forensic Medicine owes a diminution of its duties in deciding the degree of criminal responsibility of the deaf and dumb; all of whom, long held as "legal idiots" under the "perpetual pupillage of the law," were disabled from making a contract, will, or valid marriage. Possessing no institutions for their education until 1817,[5] the United States had, in 1875, forty-eight institutions, with 5309 pupils, so that "nearly all the deaf mutes of school-age within the country are now receiving instruction"; and, since "all pupils on leaving school take their places as responsible members of society, in possession of full civil rights," they cease to be of special medico-legal interest.[6]

In this, as in every civilized nation, the best examples of medico-legal progress are furnished by the institutions, laws, and decisions benefiting

[1] I have been summoned (1876), as a medical expert, to testify to my opinion as to whether a death was due to consumption, as the main issue, and, secondarily, whether due to consumption or to diphtheria.

[2] For these statistical facts I am indebted to Mr. C. C. Hine, Editor of the Insurance Monitor, No. 176 Broadway, New York City. Mr. Cornelius Walford, of London, the highest authority on this subject, has kindly furnished, for comparison with the United States, the following among other interesting facts: Life Insurance was begun in the United Kingdom (Great Britain) on a scientific basis in 1762, and reached its maximum in 1865–1868; in 1874 there were 120 companies, which issued 47,516 policies, and had in force an unstated number of total policies insuring £362,238,534. In France it was first legalized in 1787, and fettered with many legal restrictions which were removed in 1819; in 1870 there were 166,474 Life Policies, insuring £66,312,000, and 58,572 annuity contracts, securing annual annuities amounting to £1,528,600; and in 1874 there were 72 companies, having in force an unstated number of total policies insuring £49,906,400. In Germany (including German Austria and German Switzerland) Life Insurance was begun in 1827; in 1874 there were 51 companies, having in force 645,989 policies insuring a little under £100,000,000; and the new policies issued in one year (1873) were 98,692.

[3] By English law the suicide was required to be buried in a highway "with a stake driven through the body" (repealed in 1823), and his property confiscated. Juries, more humane than the law, generally decided that suicides were insane, and therefore irresponsible. Beck in 1823 (B. 209, 1st Ed.) congratulates the United States that "we do not war on the dead body in this country."

[4] The Abbé de l'Epée published in 1759 the first modern method to teach mutes, by sign-language. To him and to his disciple, the Abbé Sicard, civilization owes the initiation of the education of mutes. The first educational institution was established in France in 1760. Europe had about thirty of these institutions in 1817.

[5] The first institution founded in the United States was the American Asylum, Hartford, Conn., 1817.

[6] I am greatly indebted for the above statistical and other interesting facts to Mr. I. L. Peet, Superintendent of the New York Institution, the second one founded in the United States, viz., in 1818. (See B. 340.)

all who, no longer possessed or seduced by a legalized devil, are in fact afflicted with "unsoundness of mind," from mental disease, deformity, or debility.[1] By legislation many measures (still very incomplete in most, and not complete in any, of our States) have been adopted for the counter-protection of both the insane and the sane. The corner-stone of these measures has been the establishment of Insane Asylums. Beginning our national existence with two of these, having only eleven in 1830, we now possess about eighty public asylums, accommodating more than 30,000 of our 45,000 insane population.[2] The knowledge derived from these schools for scientific observation, is destined to benefit those without, even more than those within, their walls. Stimulated by this knowledge, the law is extending its protection, from insanity, to all who by intemperance "have lost the power of self-control." In this reform, New York, in 1854, pioneered the way with the first legislation providing for the restraint in a public asylum of habitual drunkards. In 1858, this State, as also Massachusetts, supplied the asylums indispensable for the execution of the law. With an origin thus recent, there are now at least seven asylums in five States, and four additional States have legislated to accomplish the same end.[3] The best interests of society require that this progress shall continue until the laws of every State provide for every person, whose abuse of his own liberty outrages the rights of others, ample protection both for himself and for society.[4]

Maine and New York illustrate additional progress in the jurisprudence of insanity. It is conceded that, within this century, unfortunates have been legally murdered for illegal acts, the product of disease and not of a "vicious will." To prevent these "bitter mockeries of justice," Anglo-American law, so jealous of the "liberty of the subject," fails not only to provide him, when his life is imperiled through brain-disease, with competent experts, but also to provide these with proper time and opportunity to decide a question so difficult as doubtful sanity. It is not strange that decisions reached through such defective means should cause constant dissatisfaction, nor that this should have been more serious prior to the establishment of State Lunatic Asylums; for it then occurred that he who might be acquitted of homicide, because of insanity, was freed by the law, and permitted to live a constant danger to society.[5]

Maine, in 1847, wisely enacted that "when any person is indicted for a criminal offence, or is committed to jail on a charge thereof, . . .

[1] This progress has been especially notable since 1830.

[2] For these statistics I am indebted to Dr. John P. Gray (my colleague on this occasion), who reports 54 State Asylums in 1875, accommodating 21,542 patients; 9 State Asylums in process of erection to accommodate 4600; 18 other public asylums accommodating 6064; and 10 private asylums accommodating 254 insane.

[3] Our effective Inebriate Asylums are: the Washingtonian Home, Boston, Mass., since 1858; the State Inebriate Asylum, Binghamton, N. Y., since 1858; the Inebriates' Home, King's Co., N. Y., since 1867; the Washingtonian Home, Chicago, Ill., since 1864; the Sanitarium, Media, Pa., since 1867; the Harlem Asylum for Inebriates, Baltimore, Md., which was opened in 1871; and the Franklin Reformatory Home for Inebriates, in Philadelphia, Pa., opened in 1872. California enacted the requisite laws in 1870, and Connecticut in 1874. It is believed that Texas and Kentucky have legislated on the subject. For the facts stated I am indebted to Dr. Albert Day, Sup't of the Washingtonian Home, Boston; to Dr. D. H. Dodge, Sup't of the Binghamton Asylum; and to the Annual Reports (since 1871) of the "American Association for the Cure of Inebriates."

[4] In connection with intemperance, it deserves record that only within the present century have Anglo-American Judges inclined to admit drunkenness in extenuation of crime, depriving it of premeditation. (See B. 329, p. 567.)

[5] B. 319, I. p. 759. An eminent lawyer asserts that this still occurs in some of the States, notwithstanding the State Lunatic Asylums.

any judge of the court before which he is to be tried, when a plea of insanity is made in court, or he is notified that it will be made, may . . . order such person into the care of the superintendent of the insane hospital, to be detained and observed by him till the further order of the court, that the truth or falsity of the plea may be ascertained." New York, in 1874, enacted laws which provide for "an investigation of the sanity or insanity of the accused, as a separate and independent proceeding from the trial of the indictment," and, after such preliminary investigation, "leave the question of the guilt or innocence of the accused to be tried by itself."[1] Thus have Maine and New York lessened the frequent difficulty of choosing between "inhumanity to disease, and indulgence to crime."

Five States[2] have aided the solution of this problem by progress in another direction. For, by the abolition of capital punishment, the cruel alternative between the asylum and the gallows has been obviated, and no shocking injustice can be perpetrated by confining in a penitentiary, rather than in an asylum, him proved dangerous to society. It was a great advance in civilization when the victor ceased to slaughter, and by enslaving utilized the lives of the vanquished. Will it not be proof of like progress when society has fully learned how best to utilize the lives of all its criminals?[3]

Notwithstanding that there is still great lack of uniformity in the decisions of our courts as to what are the proper tests of insanity, there has been decided progress. Until Pinel's day (1792), insanity had never been properly studied, hence physicians were little less ignorant and superstitious in regard to it than the public. In the absence of medical knowledge, what could the law do other than establish tests for itself? Until 1800, the savage test of Anglo-American criminal law was that he alone should be adjudged insane, who was "totally deprived of his understanding and memory, and did not know what he was doing any more than an infant, than a brute, or wild beast." In 1800, it was, for the first time, mercifully decided that those whose crimes were due to an "insane delusion," should not be hung, even though not yet wild beasts.[4] In 1812, it was decided that the correct test was whether the criminal alleged insane had, as to matters generally, "the power of distinguishing right from wrong;" and since 1843, in England, and to a large extent in this country, the judges' test has been, whether such criminal had, as to his special crime and at the moment it was committed, "a sufficient degree of reason to know that he was doing an act which was wrong."

But, since 1800, alienists have taught, in constantly increasing number, that a capacity to distinguish right from wrong is an inadequate test,

[1] B. 364.

[2] Michigan in 1846; Rhode Island in 1852; Wisconsin in 1853; Iowa in 1872; and Maine in 1876. Blackstone, referring in 1769 to England's "dreadful list of 160 capital offences," hoped for "such a gradual scale of punishment to be affixed to all gradations of guilt, as may in time supersede the necessity of capital punishment, except for very atrocious crimes." (Book IV. p. 371.) In the various States, other than the above, capital punishment is now inflicted for only from three to eight "very atrocious crimes."

[3] My brief allusions to the "abolition of capital punishment" and to "moral mania," intimate convictions which may cause misapprehension. For *until* our present defects in the administration of justice, in the constitution of our juries, and in the means needed to fully protect society, be remedied, I shall believe that our courts have gone generally as far as, and often much further than, the best interests of society require.

[4] In 1800, Lord Erskine initiated the first enlightened legal discussion of insanity; and the Attorney-General of England then declared that the "wild beast theory" of Lord Hale had never been contradicted, but had always been adopted.

and that, not infrequently, while the reason is apparently able to make this distinction, the will may be so enfeebled, and the morals so perverted by disease, as to deprive the sufferer of that "vicious will" necessary to constitute a crime. The first Anglo-American judges to adopt these lessons of medical science, were Shaw, of Massachusetts, in 1843, and Edmonds, of New York, in 1845. They ruled that insanity was proved if the homicide "had no power of control;" "if his moral or intellectual powers were so deficient that he had not sufficient will;" and "if he did the act from an irresistible and uncontrollable impulse."[1] The learned Edmonds took occasion to observe that "the law in its slow and cautious progress still lags far behind the advance of true knowledge," and the history of the progress of Legal Medicine proves the truth of this observation as to every medico-legal topic. How can this be otherwise while, as another legal authority asserts, our "legislatures are much better versed in the miserable tactics of party, than in the . . . laws of physiology," and while judges, as well as legislators, mindful as they should be of precedent, that friend to uniformity and stability of the law, do, in their superstitious reverence, often forget, not only that "the law of nature, being coeval with mankind and dictated by God himself, is of course superior in obligation to any other,"[2] but also that science is constantly engaged in revising and adding to our knowledge of this supreme law, thus increasing man's power to "think the thoughts of God!"

Improving on Shaw and Edmonds, Judges Bell, Perley, Ladd, and Doe, of the Supreme Court of New Hampshire, have, since 1864, announced the only principles worthy of both legal and medical science,[3] and have thereby merited the profound gratitude of the medical profession, and lasting commemoration in the annals of Anglo-American Medical Jurisprudence. None announced the true principles of the law more clearly than Judge Doe, who (in 1869) charged that "at present, precedents require the jury to be instructed by experts in new medical theories, and by judges in old medical theories;" and that, in this, "the legal profession were invading the province of medicine, and attempting to install old exploded medical theories in the place of facts established in the progress of scientific knowledge." But, he adds, "that cannot be a fact in law which is not a fact in science; that cannot be health in law which is disease in fact; and it is unfortunate that courts should maintain a contest with science and the laws of nature upon a question of fact, which is within the province of science, and outside the domain of the law." "The legal principle, however much it may formerly have been obscured by pathological darkness and confusion, is, that a product of mental disease is not a contract, a will, or a crime. It is often difficult to ascertain whether an individual has a mental disease, and whether an act was the product of that disease, but these difficulties arise from the nature of the facts to be investigated, and not from the law; they are practical difficulties to be solved by the jury, and not legal difficulties

[1] In the record of progress in the legal tests of insanity, it deserves notice that Drs. Gooch and Combe, about 1830 (B. 226), "first announced the great principle that the mind of one supposed insane should be compared with his own mind when in its natural, habitual state," and not with some ideal average mind of health. This principle has been extended by the laws of New York to homicide in self-defence, etc., modifying the interpretation of "apparency of danger," "cooling time," "intent," and "premeditation." (See Homicide; by F. Wharton, 2d Ed., 1875.)

[2] Blackstone, I. p. 41.

[3] State *v.* Wier, State *v.* Pike, State *v.* Jones, Boardman *v.* Woodman, 1864, 1869, 1870.

for the court." "If the tests of insanity are matters of law, the practice of allowing experts to testify what they are, should be discontinued; if they are matters of fact, the judge should no longer testify without being sworn as a witness, and showing himself qualified to testify as an expert." In fine, all symptoms and all tests of mental disease are purely matters of fact to be determined by the jury from the evidence of competent witnesses; and since "legal precedent was one way, legal principle the other," precedent should be abandoned, and principle be followed.

Side by side with the enlightened views of these American judges, will be recorded, for the instruction of astonished posterity, that as late as 1862 the Lord Chancellor of England did, in referring to insanity, declare in the House of Lords that "the introduction of medical opinions and medical theories into this subject has proceeded upon the vicious principle of considering insanity as a disease," and that he condemned "the evil habit which had grown up of assuming that it was a physical disease"![1] Can this fail to revive the recollection that ninety-three years anterior to this Lord Chancellor, Blackstone, an abler lawyer than he, thus fulminated (1769): "to deny the possibility, nay, actual existence of witchcraft and sorcery is at once to flatly contradict the revealed word of God," . . . "and the thing itself is a truth to which every nation in the world hath in its turn borne testimony"?[2] This Lord Chancellor affords, however, a psychological lesson much needed even now; for his opinions illustrate what profound furrows the ancestral bigotry and superstition of centuries can plough into even the best endowed brains of the descendants—as we all are—of uneducated barbarians.[3]

One more hopeful example must close my record of our progress. In 1867, Medicine and Law, uniting for the first time in history for such a purpose, founded "The Medico-Legal Society of New York;" now numbering among its members more than four hundred physicians and lawyers of influence and distinction, its brief life has been adorned with good deeds. It has established a medico-legal library, which promises to become, if it is not already, the best in existence; it is about to issue a second volume of valuable essays, the first having been published in 1874; it has, by critical vigilance, elevated the standard of medical experts, and in one noted conviction its criticisms instigated a second trial with acquittal; wisely imitating its junior, "La Société de Médecine Légale de France,"[4] in its efforts to furnish a substitute for the negligence of the State, it has (May, 1876) appointed three medical and three legal experts as a permanent commission to investigate any medico-legal issue referred to it; it has called attention to the condition and criminal responsibility of uneducated mutes, and to the laws necessary for their protection; and it has influenced the legislation of New York as to abortion, as to robbery under the influence of chloroform, and as to the trial and punishment of all homicides, whether sane or insane. Thus instructing the public, and inaugurating reforms, it seems destined

[1] Hansard, CLXV. 1297. [2] Blackstone, IV. p. 60.

[3] It deserves record, in connection with the progress of judicial decisions, that, at the present day, Anglo-American law does not regard the killing of an infant prior to its complete expulsion from the vagina (*i. e.* to its being "fully born alive") as infanticide. An English Judge recently charged a jury that, "if of opinion that the prisoner had strangled her child before wholly born, she must be acquitted of murder." (See B. 292, I. p. 542; and B. 358, II. pp. 359-61.) Ellwell (B. 290, p. 555) says, "Infanticide may be committed upon an unborn live child."

[4] Organized February, 1868, and formally recognized by a decree of the French government, January, 1874.

to render New York the pioneer of all the States in medico-legal progress; and finally, in promoting scientific intercourse and discussion between the two professions, it has forcibly taught that the invidious bigotry of the one is as misplaced as that of the other, and that the common weal loudly demands the united efforts of the best minds of both.[1]

What labor so god-like as the dispensation of justice; what efforts in its behalf can be more important than those designed to enable the law to reap promptly the full benefits of science—of that knowledge which, having done so much for human development, now proffers unappreciated boons, and by incessant progress assures mankind a higher destiny? Shall medicine and law, standing aloof, not only endure but even blindly honor ancestral evils? Is it needful in 1876 to remind two learned professions that the author of our imperishable Declaration of 1776 declared: "The Gothic idea that we are to look backwards instead of forwards for the improvement of the human mind, and to recur to the annals of our ancestors for what is most perfect in government, in religion, and learning, is worthy of those bigots in religion and government by whom it has been recommended, and whose purposes it would answer. But it is not an idea which this country will endure"?

This historical sketch requires for its completion a record of the measures proposed to correct our medico-legal evils, which, often denounced since 1823 by the medical profession, continue unappreciated by the people. To test the value of these proposed measures it is indispensable to understand the following premises, accepted by the highest medical and legal authorities.

While one would suffice to maim, our law adopts two methods to murder, Medical Jurisprudence; both so result that it is a vulgar mockery of medical knowledge and of justice to term such medical evidence as is attained, "the best attainable." In one case, the law neglects to secure competent experts to testify, as "ordinary witnesses," to facts obtained by them from inquests and all medico-legal examinations. In the other case, the law fails to provide such experts to testify, as "skilled witnesses," not to facts they have personally witnessed in the case, but to their "opinions," as to what conclusions are deducible from the medical facts sworn to by ordinary witnesses; for this marked difference between the *ordinary* and the *skilled* witness, Anglo-American law deplorably fails to make any provision, while German and French law wisely recognize that the skilled witness is not an ordinary witness, but an *arbitrator*. Further, it is manifest that the experts thus needed, for two distinct purposes, can never be supplied except by the State; that the competency of these experts can never be secured except by special and practical instruction; that the chief instruction must be given by medical men; and that the instructors alone are competent to attest the competency of their pupils.

These premises cannot be refuted, and force the general conclusions that no measures could fully correct our evils except such as, in the first place, would reform altogether the office of coroner, and supply competent experts for its duties, and, in the second place, would provide a legal status for skilled witnesses, and secure their skill; and that these two indispensable ends can never be gained except through *an organized system of medico-legal officials, specially trained as medical experts, and*

[1] B. 356, 363, 364, 380, 387.

attested as competent by competent judges. Alas! these irrefutable conclusions are most discouraging, for no American can fail to appreciate how difficult and distant is their realization. But when the remedies are not forthwith at hand to cure a disease, should we cease its study, and our efforts both to discover and to obtain all the remedies necessary? A full understanding of the indispensable remedies, will at least enable us to test the value of the seven which have been proposed. Their introduction requires two comments: first, there is no one of them which would not prove decidedly beneficial, since, fortunately in this regard, there is no change of our law which could possibly aggravate our present evils; and second, the first four to be mentioned apply to only one of our two great evils.

One proposal is that special juries be provided for special cases,[1] and another is that a medical assessor be appointed to advise and assist the courts;[2] either would provide better judges of medical testimony, but neither makes any attempt to supply "the best attainable evidence." A third measure proposes a commission of experts chosen either by mutual consent,[3] or one by each party and a third by the judge.[4] This great improvement could probably be adopted more readily than any other measure suggested; but none of those thus authorized to appoint have the knowledge necessary to enable them to select competent experts, and therefore this measure would certainly not secure "the best attainable evidence." A fourth proposal is the adoption of the French law which empowers the judge to appoint a medical commission.[5] French authorities, while urging the adoption of the German system, denounce their own with even contemptuous bitterness,[6] asserting that their judges rarely appoint competent experts, but generally their own family-physicians and practitioners of merely popular repute.[7] A fifth proposal, which would require all graduates in medicine to be competent experts, as well as practitioners,[8] has long been, and is daily becoming so much more impracticable, as to deserve no notice except as illustrating how inadequately is estimated the extent and character of the special knowledge necessary to a medico-legist.

Prof. Gross[9] urged, in 1868, that the Judges of the Supreme Court of each State should appoint a commissioner in every judicial district, to elicit and estimate medical evidence; and that he should be provided with two or more medical experts as assistants, to make all medico-legal examinations. This is the only measure, thus far considered, which aims a practical blow at both our evils. But, if French experience be applicable to us, then judges of law are not good judges of experts, and should not be authorized to appoint them, except from those whose competency has been attested by competent judges of experts; and, if German experience be applicable to us, then a medical commissioner, long ago tried

[2] A. S. Taylor and many others.
[3] Beck (B. 209) and others.
[4] Ordronaux (B. 318), etc.
[5] Urged by many.
[6] See Foderé, Orfila, Devergie (B. 114, 121, 124); and especially the Preface to Vol. I. 4th ed. of Orfila. Some at least of the French courts have made the improvement of appointing a permanent commission of experts for all medico-legal cases, instead of a special commission for each case.
[7] If the French system be satisfactory, if the State provide, as it should, "the best attainable evidence," then why should there be in Paris, as in New York City, an unofficial and gratuitous commission of volunteer experts?
[8] Chitty (B. 231), and very many others.
[9] President's Address, Trans. Am. Med. Assoc., 1868.

and abandoned in Germany,[1] is superfluous, provided the law supplies a proper system and competent experts to present to the courts "the best attainable evidence."

Finally, others advocate some such modification, as may be practicable under our form of government, of that German system which, the growth of two centuries of experience, alone gives satisfaction at home, and at the same time commands the admiration of the medico-legists of every civilized nation.[2] The Prussian system has four grades of medico-legal officials. (1) To a specially educated official expert is submitted every medico-legal case.[3] His examinations, made in presence of the judge (in some cases), and of medical men and students, insure by their publicity thoroughness and impartiality, and are the foundation of Germany's medico-legal clinics which provide the practical instruction indispensable to the education of competent experts. All the facts and proofs derived from the examination, and essential to a conclusion, are made parts of a written report, and these reports, with subsequent action thereon, are preserved in official archives, and have been the source of Germany's fruitful medico-legal literature. (2) If prosecution or defence be dissatisfied, the expert's report, with all proofs preserved, is forwarded to a Medical Court of Appeal, which, consisting of from four to six members, exists in each province. (3) If this second decision prove unsatisfactory, there is a final appeal to a Scientific Deputation, composed of experts of national reputation.[3] (4) Finally, one of the highest officers of the government, the Minister of Medical Affairs, presides over an educational and a sanitary, as well as over this medico-legal organization, and in fact rules a department of State Medicine.

Has State Medicine become necessary to a nation's progress in civilization? Can services essential to the welfare of a people be rendered by other than medical officers? Who will deny that no well-governed State can dispense with medical instructors; with physicians in charge of its hospitals and asylums; with medico-legal experts; with inspectors to watch over the execution of proper laws for prohibiting quackery and the sale of quack, fœticidal, poisonous, and adulterated drugs and food, and also to certify to every death with its cause, after personal examination;[5] with registrars of vital statistics to record not only marriages,

[1] See Preface to the French edition of Casper (B. 88).

[2] Sheldon Amos, Esq., Prof. of Jurisprudence, University College, London (see "Science of the Law," New York, 1874), in discussing the expert problem, says: "Almost all the solutions point to the public organization of bodies of skilled witnesses in each of the important departments in which they are constantly demanded, and to a special preference being given to their evidence in the administration of justice." Francis Wharton, Esq., (B. 264, II. p. 1120) urges that the German system is the only one worth imitating. In these views I thoroughly concur, notwithstanding the serious objections urged by such high authorities as J. Fitz Stephen, Esq., and I. Ray, M.D.

[3] There are circumstances, says Casper, where any doctor may be called on, as an expert, in Prussia.

[4] Formerly in Prussia (probably still in parts of Germany) the collegiate medical faculties were appealed to, whenever the primary reports of the official experts were not satisfactory to both litigants.

[5] The English system of determining and certifying to death and its cause is certainly not inferior to any such system (or lack of system) existing in the United States; and yet so inefficient is this superior system that Prof. A. S. Taylor reports that a man registered his own death, and then based a fraudulent claim on the certificate of his death and on the fact of his burial, which he himself had supervised; and he further asserts that "all that is requisite for future murderers by poison to do, is to use small doses, combine the use of various drugs, and subpœna the proper medical witnesses for the defence." (See B. 358, I. pp. 167–8 and 196.)

births, and deaths, but also prevailing diseases with their causes; and, finally, with sanitary officers to guard the public health by vaccination, quarantine, seclusion, disinfection, and all known means?

While such services to the State would now confer incalculable benefits, these are not a tithe of those which the progress of medical science assures the future. But a patchwork of ill-digested laws cannot secure these benefits, nor mere practitioners of medicine render these services. To this end a well-organized system of State Medicine, administered by specially educated medical men, is indispensable; and however discouraging the difficulties, educational, legal, and political, in our path, these must be eventually overcome, or our country prove a laggard in the triumphant march which civilization, led by the hand of science, is now treading. One of these difficulties, an increase of officials, dangerous to a republic, repugnant to the people, is more serious in appearance than in reality; for our present posts for coroners, and for sanitary and other medical officers, would suffice for, at least, the initiation of an organized system of State Medicine. Far more serious difficulties are presented by those causes which now so often fill these posts with unqualified men, by the continual elections and "rotations in office," through which the people, with suicidal folly, eliminate from public service responsible and efficient servants. If the demoralizing political principle, "to the victors belong the spoils," is to continue its mastery over the virtue and intelligence of a great people, then all hope of efficiency in any system of State Medicine, as well as in every public service which requires special skill and experience, must be abandoned. But, if the cardinal maxim of our political faith be well founded, if it be true that a republican government is better adapted than any other to secure the greatest good to the greatest number, then, though public enlightenment develop slowly, the day must come at last when all impediments will be overthrown, and an efficient system of State Medicine be organized by our laws. This progress, as all others, must pass through stages of evolution, and expediency force the acceptance, as now, of mere make-shifts; but this conviction should not deter the attempt to measure the full extent of our defects and of our needs, nor prevent us, while conscious that we are but scratching the surface of great evils, from striving to direct our efforts to their very root.

Honored Members of this International Medical Congress: Laboring on the task now completed, professional instinct prompted as sedulous a search for the symptoms of disease which skill might alleviate, as for the evidences of health which need no aid; for the instruction of my successor of 1976 (the one man who, should there be no other, will study this Address), I have deemed it as needful to record that which has been left undone, as that which has been done; and, while mindful of gratitude's debt to the honored living and illustrious dead, I have endeavored to keep in mind that the chief object of history is to teach wherein and why we have failed, that we may do better in future.

Actuated by these motives, I have thought no time more appropriate to note our failures than this Centennial Year, which gathers from far beyond our own vast domain, conclusive evidences of the might and fame of this nation. To its colossal power, how harmless is the voice of malice; to its dignity, how offensive should be the voice of flattery; to its honor, how unwelcome aught save the voice of truth! What higher evidence of true greatness, what better pledge of continued prosperity,

can this people give, than by proofs that now, in the day of its supreme vigor and renown, it is intent upon its own shortcomings; and that, beneath a flimsy veil of national vanity, there sturdily stands "the pith o' sense, and pride o' worth"! If I have dwelt unduly on my country's faults, it has not been from lack either of devotion to its form of government, or of just pride in its many noble deeds in humanity's behalf; but that I would have our Republic foremost in every good work, its progress endless, and its glory deathless.

BIBLIOGRAPHICAL APPENDIX.

Explanations and Abbreviations.

To economize space, the titles and places of publication of the general treatises in foreign languages have been omitted, except in a few instances of those of great note. For the same purpose, each author has been numbered, and is referred to by number in the notes to the Address, and in the final indices to this bibliographical appendix. Dates separated by a hyphen, *e.g.* 1621–58, indicate that the publication of the book in different parts was begun in 1621, and completed in 1658; dates separated by a comma, *e.g.* 1598, 1602, 1671, indicate the dates of the publication of different editions; and dates repeated, or closely approximating, indicate the publication of different editions in different places.

This contribution to the bibliography of American Medical Jurisprudence is preceded by a bibliographical record of the medico-legal literature of Italy, Germany, France, and Great Britain; and the whole has been arranged chronologically to illustrate the origin and progress of medico-legal science.

Wildberg's "Bibliotheca Medicinæ Forensis, 1819," records 2980 treatises, essays, etc., published from the origin of medico-legal literature (about A. D. 1600) to 1818. Orfila's Médecine Légale, 4th ed., furnishes a list of 168 treatises (to 1848), on poisons generally; of these 100 were German, 33 French, and 19 English. An English authority, the New Sydenham Society's "Year Books" for 1859 and 1860, reports the chief literary contributions of all nations to Medical Jurisprudence and Toxicology during the two years 1858 and 1859; the total number was 498, viz., 250 for Legal Medicine and 248 for Toxicology: and of the former, Germany contributed 201, and of the latter, 118. These, with other facts, indicate that Germany continues to contribute more to medico-legal literature than all other nations combined; and that a complete bibliography of the Medical Jurisprudence of all languages must report many thousands of books, essays, and articles. Hence the bibliographical sketch of foreign literature attempts no more than the record of treatises and manuals on the general subject; preceding these with a list of the books on special subjects which were published prior to the first general treatise; and following these with a reference to a few authorities of great repute on special subjects. It deserves note that in every language the number of publications on special subjects, after the issue of the first general treatise, has been very great, and proportionate to the number of general treatises.

The contribution to the bibliography of American Medical Jurisprudence attempts to report all the treatises, books, essays, and pamphlets, by native and foreign authors, published in the United States; the republication of foreign works being indicated by a †. Only a few articles from Journals are cited, and these for a special purpose. The bibliography of Medical Jurisprudence, as represented by "articles in journals, transactions, and collections," giving "the results of the examination of about 5000 volumes of such publications," will constitute a part of the "Catalogue of the National Medical Library," now in course of preparation by Dr. John S. Billings, Asst. Surgeon U. S. A., and Librarian; and will probably be published in 1877. Further, the New

York Medico-Legal Society is preparing for publication an extensive bibliography of Medical Jurisprudence. These two sources will no doubt supply all defects and omissions in this contribution.

For articles and reports of merit, the reader is referred especially to the American Jurist and Law Magazine, Boston, 1829 to 1843; American Journal of Insanity, Utica, N. Y., since 1844; Reports of the Association of Medical Superintendents of Hospitals for the Insane in North America, since 1844; Transactions of the Medical Society of the State of New York, prior to 1845; Transactions of the American Medical Association, since 1848; Albany Law Journal, since 1870; Annual Reports of the American Association for the Cure of Inebriates, since 1871; the Psychological and Medico-Legal Journal, N.Y., and the Series of Papers by the N. Y. Medico-Legal Society, both since 1874.

ITALY.

General Treatises.—1. Fidelis, Fortunatus, De Relationibus Medicorum, 1598, 1602, 1671. 2. Zacchias, Paulus, Questiones Medico-legales, &c., Books I. to X., 1621–58, 1651, 1655–61, 1657, 1666, 1688, 1674–1701; Nuremberg, 3 vs. 1720; Venise, 1737. 3. Tortosa, "best book to its date," 2 vs. 1802, 1809. 4. Sidoti, 1806. 5. Barzelotti, "very excellent," 2 vs. 1818, 1823–4, 1839. 6. Martini, 3 vs. 1825. 7. Taurini, 4 vs. 1832, 1841–4. 8. Speranza, 1833. 9. Grotanelli, 1834. 10. Clédillot, 1836. 11. Riscica, 1836. 12. Gianelli, 1836. 13. Perrone, 2d ed. 1840. 14. Presutti, 1841–4. 15. Treschi, 3 vs. 1846. 16. Lazzaretti, 1859. 17. Gandolfi, 1854, 1863.

Special Treatises.—18. Morgagni, De Sedibus et Causis Morborum, 1761. 19. Beccaria, Scriptura Medico-Legalis, 1764; and "Crimes and Punishments;" republished in Italian, 1821; French, 1821; English, 5th ed. 1804; Philadelphia, 1778 and 1793.

GERMANY.

Earliest Treatises on Special Subjects.—20. Condronchus, Methodus Testificandi, 1597. 21. Libavius, De Cruentatione Cadaverum, 1599. 22. Ammann, Irenicum, &c., 1619, and Medicina Critica, 1677. 23. Behrens, Medicus Legalis, 1696. 24. Wolf, Cogitat. Med.-Leg. 1697. 25. Valentini, Pandectæ Med.-Leg. 1701, and Novellæ Med.-Leg. 1718. 26. Fischer, Consilia Medic., &c., 1703–6, and Responsa Pract. et Forens. Select. 1719. 27. Bohn, De Officio Medici, 1704, and De Renunciatione Vulnerum, 1689, 1710 (both of note). 28. Zittman, Medicina Forensis, 1706.

General Treatises.—29. Valentini, Corpus Juris. Med.-Leg. ("best book to its date"), 2 vs. 1722. 30. Teichmeyer, Institutiones Med.-Leg., &c. ("long the Manual of Students"), 1722, 1731, 1740, 1762, 1769. 31. Albertus, Systema Jurisp. Medicæ, &c. ("very excellent"), 1725, 1733–47, 1756. 32. Goelicke, 1723. 33. Loew, 1725. 34. Storck, 1730. 35. Tropanneger, 1733. 36. Eschenbach, 1746, 1775. 37. Hebenstreit, Anthropologia Forensis, &c. ("much valued by lawyers"), 1751. 38. Furstenau, 1752. 39. Boerner, 1756. 40. Bernhold, 1760. 41. Ludwig, 1765, 1774. 42. Faselius, Elementa Medicinæ Forensis, 1767, 1775 ("*foundation*" of Farr's Elements of Med Jurisp., 1788, the first treatise in the English language). 43. Braendel, 1768, 1789. 44. Kannegiesser, 1768, 1772, 1777, 1778. 45. Baumer, 1778. 46. Sikora, 1780, 1792. 47. Plenck, Elementa Med. et Chir. Forensis, 1781, 1786, 1802 (foundation of Male's Epitome of Forensic Medicine, London, 1816). 48. Haller, 1782–4. 49. Schlegel, Collect. Opusc. Select. ad Med. For. Spect., 6 vs. 1785–90 ("best book to its date"). 49. Loder, 1793. 50. Metzger, System. der gerichtl. Arzney. ("best book to its date"), 1793, 1794, 1798, 1803, 1814, 1820, and two French editions: Autun, 1812; Paris, 1813. 51. John, 1795. 52. Fahner,

3 vs. 1795–1800. 53. Müller, 4 vs. 1796–1802. 54. Erhard, 1800. 55. Schrand, 1802. 56. Schmidtmuller, 1804. 57. Masius, 1810, 1812, 1821–3. 58. Bene, 1811. 59. Wildberg, 1812, 1824. 60. Henke, Lehrb. der gerichtl. Med., 1812, and Bergmann's 13th ed., 1859. 61. Niemann, 2 vs. 1813. 62. Bernt, 1813, and 5th ed. 1846. 63. Dorn, 1813. 64. Klose, 1814. 65. Sprengel, 1816. 66. Mende, Handb. der gerichtl. Med. ("a remarkable book"), 6 vs. 1819–32. 67. Meckel, 1821. 68. Platner, 1824. 69. Niemann, 3 vs. 1827–9. 70. Wagner, 1833–40. 71. Sporer, 1837. 72. Siebenhaar, 2 vs. 1838. 73. Freidreich, 2 vs. 1839, 1843, 1848, 1855. 74. Rolff, 1840. 75. Nicolai, 1841. 76. Ney, 1845. 77. Bergmann, 1846. 78. Brach, 1846, 1850. 79. Siebold, 1847. 80. Meckel, 1848–53. 81. Schürmayer, Lehrbuch der gerichtl. Med., 1848, 4th ed., 1874. 82. Quentner, 1851. 83. Güntner, 1851. 84. Krahmer, Handb. der gerichtl. Med., 1851, 1857; and 85. Handb. der Staatsarzneik., 1874. 86. Böcker, 2d ed., 1857. 87. Hauska, 1857–69. 88. Casper, Handb. der gerichtl. Med., 1857, 1858; 3d was the first complete ed., 1860, 1864; Liman's 5th ed., 1871; French ed., 2 vs. 1862; English ed., 4 vs. 1861–5; and translated into several other languages. 89. Hofman, 1860. 90. Pichler, 1861, 1867. 91. Lion, 1861, 1867. 92. Schauenstein, 1867. 93. Büchner, 1867; 2d ed., 1872. 94. Kraus und Pichler, Encyc. Wörterbuch d. Staatsarzneik., 2 vs. 1873.

N. B.—Five of the above sixty-five German general treatises have been published since 1870, viz.: Casper (Liman's 5th ed.), 1871; Büchner, 2d ed., 1872; Kraus & Pichler, 1873; Krahmer, 1874; Schürmayer, 4th ed., 1874.

Special Treatises.—Among the most distinguished German authors on special subjects have been: 95. Roose, Grund. Med.-gericht Vorles., 1798, 1800, 1802; translated into French by Marc, Manuel d'Autops. Cadav. Méd.-Lég., Paris, 8vo. 1808. 96. Hoffbauer, 1802, 1807, 1809; translated into French, Méd. Lég. relative aux Aliénés, &c., Paris, 1827. 97. Heinroth, 1812, 1825. 98. Mittermaier, 1856, 1858, 1865. 99. Krafft-Ebing, 1868, 1872, 1875. All of these in reference to the Medical Jurisprudence of Insanity or Medico-Legal Psychology.

France.

Earliest Treatises on Special Subjects.—100. Paré, Ambroise, Medical Reports, Monstrous Births, Feigned Diseases, 1575, 1582, and Œuvres Complètes, Paris, 3 vs. 1840. 101. Pineau, Integ. et Corrup. Virgin., 1598. 102. Riolan, Les Monstres, 1605. 103. Tagereau, L'Impuissance, 1611. 104. Duval, L'Hermaphrodisme, 1612. 105. Sebitz, La Virginité et L'Hymen, 1630, 1638. 106. Gendri, Moyens de bien rapporter à justice, 1650. 107. Blegni, La Doct. des Rapports de Chirurgie, 1684. 108. Devaux, L'Art de faire des Rapports en Chirurgie, 1693, 1701, 1730, 1746. 109. Bruhier, L'Incertitude des Signes de la Mort, &c. (180 cases of living, treated as if dead), 1742. 110. Verdier, La Jurisp. de la Méd., &c., 1752. 111. Prévost, Principes de Jurisp., &c., Méd.-Lég., 1763. 112. Louis, A. Signes de la Mort, &c.; Exps. sur les Noyés; Recueil d'Observations, &c.; Causes Celèbres (first 43 vols.), 1752–88. 113. Chaussier, Obs. Chirur.-Légales, &c., 1790, 1824, 1838.

N. B.—The most noted of these were Paré, Gendri, Blegni, Devaux, Louis, and Chaussier.

General Treatises.—114. Foderé, Traité de Méd. Lég. et d'Hyg. Pub., 3 vs. 1796; 2d ed., 6 vs. 1813. 115. Mahon, 1801, 1807, 1811. 116. Belloc, 1801, 1811, 1819. 117. Vigné, 1805. 118. Bertrand, 1817. 119. Lecieux, &c., 1805. 120. Biessy, 1821. 121. Orfila, Leçons de Médecine Légale, 3 vs. 1821–5, 1828, 1839; 4th ed., 1848. 122. Briand, Manuel de Médecine Légale, 1821, 1828; Briand et Bresson, 3d ed., 1830; Briand et Chaudé, 1846, 1852, 1858, 1864, 1869; Paris, 9th ed., pp. 1102, 8vo. fort., 1874. 123. Sédillot, 1830, 1833. 124. Trinquier, 1836–8. 124*a*. Devergie, Médecine Légale, 3 vs. 1837, 1840, 1852. 125. Bayard, 1844. 126. Legrand du Saulle, Ortolan, et Naquez, 1870.

127. Legrand du Saulle, Traité de Médecine Légale et de Jurisp. Méd., Paris, pp. 1268, 1874. 128. Bergeron, 1876.

Special Treatises.—Among the most distinguished French authors on special subjects may be mentioned: 129. Pinel, Ph., 1800, 1805, 1809. 130. Georget, 1820, 1826, 1828. 131. Esquirol, 1832, 1838. 132. Marc, 1840. 133. Brierre de Boismont, 1827–1860. (All on Medico-Legal Psychology.) 134. Capuron, Obstetrical Medical Jurisprudence, 1821. 135. Trebuchet, Jurisp. de la Médecine, &c., 1834. 136. Poilroux, Manuel de Méd.-Lég. Criminelle, 1834, 1837. 137. Tardieu, A., numerous experimental and literary contributions, entitling him to the first rank among the medico-legists of the present time, 1845 to 1876.

GREAT BRITAIN, ETC.

Earliest Treatises on Special Subjects.—138. Percival, Thos., Essays Med. and Exp., &c., 1778–90. 139. Wm. Hunter, Uncertainty of Signs of Murder in Bastard Children, 1783. 140. Goodwyn, Submersion, Strangulation, &c., 1788. 141. Crichton, Mental Derangements, 1798. 142. Haslam, Insanity, and Medical Jurisp. of Insanity, 1798, 1809, 1817, 1819. 143. Johnstone, Madness, Med. Jurisp. of, 1800. 144. Perfect, Insanity, 2d ed., 1801. 145. Collinson, Lunacy, Law of Idiots, Lunatics, &c., 1812. 146. Johnson, C., Signs of Murder in New-Born Children (from the French of Mahon), 1813. 147. Hill, Insanity, 1814. 148. Hutchinson, Infanticide, 1820. 149. Burrows, Insanity, 1820, 1828.

General Treatises.—150. Farr, Saml., Elements of Medical Jurisprudence (founded on the German of Faselius, 1767, see 42), London, 12mo. 1788; 2d ed., pp. 139, 12mo. 1814. 151. Bartley, Treatise on Forensic Med. (said to be very insignificant), Bristol, 12mo. 1815. 152. Male, Epitome of Forensic Medicine (largely from the German of Plenck, see 47), London, 12mo. 1816; 2d ed., 1818. 153. Smith, John Gordon, Principles of Forensic Medicine (the first book in the English language of any original merit), London, pp. 503, 8vo. 1821; 2d ed., 1824; 3d ed., 1827. 154. Paris and Fonblanque, Medical Jurisprudence (best book to its date), London, 3 vs. 1823. 155. Forsyth, Synopsis of Modern Medical Jurisprudence (denounced by Beck as a wholesale plagiarism), London, pp. 600, 1829. 156. Ryan, Manual of Med. Jurisp., London, pp. 309, 8vo. 1831; 2d ed., 1836. 157. Chitty, Med. Jurisp. (never completed), London, Part I. 8vo. 1834. 158. Traill, Outlines of Med. Jurisp., Edinb. 12mo. 1836; 2d ed., 1840. 159. Brady, Med. Jurisp., Dublin, 1839. 160. Taylor, A. S., Elements of Med. Jurisp., Vol. I., pp. 511, 8vo., London, 1836 (a second volume never published). Manual of Med. Jurisp., 1st ed., 1844; 8th ed., 1866; 9th ed., London, pp. 772, 8vo. 1874. N. B.—Seven American and one German ed., 1858. 161. Guy, W. A., Principles of Forensic Medicine, London, 1843; 2d ed., pp. 534, 1861; 3d ed., 1868. 162. Taylor, A. S., Principles and Practice of Medical Jurisprudence, London, 1865; 2d ed., 2 vols. pp. 723, 672, 8vo. 1873. 163. Husband, Forensic Medicine and Med. Police, Edinb. 1873. 164. Woodman and Tidy, Handy-book of For. Med. and Toxicology, London, 1875.

Special Treatises.—Among the most distinguished British authors on special subjects, and whose books have not been republished in America (see 201 to 390), may be mentioned—165. Conolly, 1830. 166. Pagan, 1839, 1843—both on the Med. Jurisp. of Insanity. 167. Watson, Alex., Homicide, 1837; 2d ed., 1842. 168. Gavin, H., Feigned and Factitious Diseases, 1843.

CONTRIBUTION TO THE BIBLIOGRAPHY OF AMERICAN MEDICAL JURISPRUDENCE.

Republications of foreign works are indicated by a †, and pamphlets by a *; the latter are for the most part reprints from Journals, etc. Some works not strictly medico-legal are given, because often referred to by medico-legists.

201. †Cox, J. M. Observations on Insanity, Med. Jurisp. of, from the 2d London ed. Phila., 1811.
202. Rush, Benj. Introductory Lectures (16th). 8vo. Phila., 1811.
203. Rush, Benj. Diseases of the Mind. 8vo. pp. 367. Phila., 1812. 2d and 3d ed.? 4th ed. 1830, 5th ed. 1835.

Index to Subjects in the American Bibliography, 201 to 390.

General Alphabetical Index.

N. B.—Under each letter, the authors are recorded in the following national order: Italy, Germany, France, Great Britain, and the United States. Foreign authors, recorded among the American, are designated by a †.

For bibliographical and other aid I owe hearty thanks to my colleagues, Professors S. M. Bemiss, M.D., T. G. Richardson, M.D., Frank Hawthorn, M.D. (deceased), and to Drs. W. H. Watkins, and E. Dreifus, of New Orleans; to Dr. John S. Billings, Assistant-Surgeon, U. S. A. (Surgeon-General's Library); to Dr. Francis H. Brown, of Boston; to Professors S. D. Gross, and John J. Reese, and Dr. Joseph G. Richardson, of Philadelphia; to Mr. Clark Bell, ex-President of the N. Y. Medico-Legal Society, and Prof. W. A. Hammond, of New York City; to Prof. A. B. Palmer, M.D., of the Univ. of Michigan; to Prof. D. A. Morse, of Ohio; and to Prof. A. S. Taylor, of London, England. Obligations to others have been acknowledged in the notes to the Address.

ADDRESS ON MENTAL HYGIENE.

BY

JOHN P. GRAY, M.D., LL.D.,

MEDICAL SUPERINTENDENT OF THE NEW YORK STATE LUNATIC ASYLUM, UTICA; PROFESSOR OF PSYCHOLOGICAL MEDICINE AND JURISPRUDENCE IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

THE classical phrase, "*Mens Sana in Corpore Sano*," is a general and true expression of the related condition of the mind and body for the best functions of human life. Health of body has, in all times, been regarded as essential to the best balance and culture of mind, and to the most effective application of its activities to the concerns of the world, whether educational or practical, whether in the realm of Philosophy or in the lower plane of Manual Labor. This is true notwithstanding that there are notable exceptions where great intellectual activity and application have been conjoined with feeble physical structure, and even disease.[1]

Indeed we must start with the proposition that what is now denominated Mental Hygiene, is practically inseparable from Physical Hygiene. It is comparatively a new application of the word hygiene. Dr. Maudsley, in his Gulstonian Lectures for 1870, says: "The time has come when the immediate business which lies before any one who would advance our knowledge of mind, unquestionably is a clear and searching scrutiny of the bodily conditions, of its manifestations in health and disease." Again, "as physicians, we cannot afford to lose sight of the physical aspects of mental states, if we would truly comprehend the nature of mental disease, and learn to treat it with success. The metaphysician may, for purposes of speculation, separate mind from body, and evoke the laws of its operation out of the depths of self-consciousness; but the physician, who has to deal practically with the thoughts, feelings, and conduct of men, who has to do with the mind, not as an abstract entity concerning which he may be content to speculate, but as a force in nature, the operations of which he must patiently observe and anxiously labor to influence, must recognize how entirely the integrity of the mental functions depends on the bodily organization, must acknowledge the essential unity of mind and body."[2]

And the great change which has taken place in the views regarding insanity, within the memory of men now living, transferring it from the domain of mere metaphysics, to the jurisdiction of medical science, as a recognized physical disease, witnesses to the same thing. But notwithstanding this intimate connection of physical with psychological conditions, in the study of mental hygiene, it will not be expected that I should go into the former, or into the field immediately related, of Pre-

[1] Dr. Godman, Dr. Robert Hall, the historian Prescott, and numerous other instances might be cited.

[2] Body and Mind, pp. 1, 108.

ventive Medicine, as that whole subject has been assigned to my learned *confrère*, Dr. Bowditch, who has already explored and expounded it in the most exhaustive and satisfactory manner. My range of thought must, therefore, rather be general, and less limited by professional metes and bounds than if it were a strictly medical or a purely psychological one, and may, therefore, not prove as satisfactory to my professional brethren. I shall also be pardoned, I trust, on this National Centennial, if I refer to our own nation largely in elucidation of principles, and for practical illustrations.

This whole subject was formerly confined within the range of philosophy alone. In the days of ancient civilization, before real science was born, when the oracle "know thyself," had only a subjective metaphysical meaning, men like Plato and Cicero placed all mental hygiene in the delights of literary conversation and philosophizing. The Academic Groves were the resorts of dreamy contemplation of a State and a World that never could be realized. The Tusculan Villa was a refuge from the clamor of Senates and the wrangles of the Forum, where Cicero and his friends sought their *otium cum dignitate*, secure from the jealousies and conspiracies of politics, whether Cæsar or Pompey should triumph. They knew little of the physiological functions of the body, while they indulged in their acute and poetical, and sometimes touching, speculations upon the immortality of the soul; but modern science, in studying and dignifying the visible temple of the immortal spirit, has only confirmed and followed in the track of Christianity, which first promised to the human body an equal dowry of immortality with the human soul. The Resurrection staggered the Stoics and Epicureans; but it is at least the best warrant in the diploma of modern medical science, now perhaps somewhat disposed to spiritualize even matter itself, to endow it with the "promise and potency of every form and quality of life." On the other hand, the expression "mental physiology" has been coined to identify the study of mind with that of body, and some would even attempt to resolve all psychology into physiology.

Mental hygiene may be variously classified, but, as a whole, it embraces all that relates to the development, exercise, and maintenance of mental activity in individuals, communities and nations, and must, therefore, be considered from an individual, social, and national point of view. It involves education, social culture, religion and national life. With the individual, it begins at birth, and takes cognizance of even the constitutional tendencies, under laws of heredity, as well as of all the circumstances of subsequent life. To the individual then, in a general way, it consists in that general and special training which will most perfectly and harmoniously develop the body and the mental faculties for the duties of life. At the outset, therefore, on this point, we are met with the questions, who is the individual? What has he to do as an occupation of life? However we may settle on general principles, the rules for individuals must be special. Practically, we must consider classes and conditions. The occupation and pecuniary condition of parents; their culture, social status, and surroundings; clothing, food, and climate; proximity to schools, churches, and places of amusement; density or sparseness of population; laws, government, etc., must all be considered as among the efficient and constantly modifying conditions of any system of hygiene proposed.

Thus, it will be seen, it is a many sided and all-embracing subject, evidently too vast for one, in an address of an hour, to do more than simply

glance at its main features. Though it may be looked at from various stand-points, as men contemplate life, its duties, objects, and ends, from the work they are doing in the world, the fundamental ideas must be the same, to lead to any practical results. The views which the minister, the lawyer, the teacher, the scholar, the physician, the scientist, and the statesman, may take, will be directed, or colored somewhat, by their field of observation, and their bias of education; but on general principles they must be in accord. Mental hygiene covers all the broad field of human energy, embracing all the professions and every branch of industrial life. It looks after man's moral as well as his intellectual nature, for the two cannot be separated. It enters into his domestic and social conditions, and follows him in his duties as a citizen.

I. It first looks at *human nature*—at man as he is born—his utter helplessness, his passions, his needs, physical and mental, and his social, moral, and spiritual wants, and then must devise a scheme for his development. Is this an easy task? The science that would do this perfectly, must, from the realm of physiology, single out the laws written on his members, and harmonize them, in their development and action, with the laws of the spirit written on the psychological side of his nature, and put these in harmony with the laws of nature around him, in whose realm he dwells, and bring all in obedience and loving accord with the eternal truths of God. Mankind has been working upon this problem ever since Adam first contemplated the tree of knowledge, in the Garden of Eden, and was sent forth to his toil and to his own reflections. It will continue to be a problem, for human nature will not change; the human passions, in all their wide scope, are not to be obliterated under culture, but regulated and controlled. Indeed, the discipline of the passions is, in a large measure, the moral side of this great question. Except for speculative study, there is no separation of the intellectual and moral elements, and the regulation of the passions and their proper development become a part of education.

A fundamental principle, therefore, in mental hygiene, is harmonious intellectual and moral culture, under the recognition of man's essential nature as a spiritual being. This cultivation is imperative, in order that man may be able to recognize not only his own needs, but his relations to others; that he may, while taking care of himself, be able to see that he forms an integral part of a social organization absolutely essential for his own welfare. The machinery for the preservative harmony and elevation of social life, must reach to every class and condition; otherwise, the antagonistic elements would impede, if not prevent, all progress, and engender discord.

Common customs, common schools, and common laws, are the most fundamental, and also the most powerful, equalizing agencies in the great machinery of the politico-social life of a people. Through these means the rich and poor meet on common ground, and acquire a certain degree of unity in physical and mental training, and a certain likeness of character and harmony of thought on the great questions of education, morals, politics, and religion, highly favorable to stability, both social and national. Thus great general principles of government become more readily and universally received, and there are left for difference and discussion only the methods and forms of development and application. Still, these means only partially reach into the home life of individuals, where influences are constantly limiting and modifying development, both physical and mental. Indeed, however distinctly the laws of

physical and mental hygiene may be stated, like fundamental propositions in law and morals, their individual application may be difficult. The circumstances surrounding and controlling, may not only modify, but entirely forbid, their application; and persons, families, and whole communities, do thus drift away from any regulated plan of life, or any reasonable principles of action, as the history of moral epidemics, not only in the past but the present, would abundantly show. Poverty and ignorance, the breeders of vices and crimes, and the enemies of culture, may render all principles nugatory, except as they are enforced by law. And in this direction political economy is a most important element in the study of mental hygiene, in its broad application to the interests of mankind.

Thus we see in hygienic science the ideas which lead to the study of pauperism and crime, and the care of the dependent classes, whether made so by disease or misfortune; to the origination of means for preventing social evils of every character; to the enactment of laws for the regulation of morals by limiting vices, as in licensing prostitution and the sale of intoxicating drinks; laws for the suppression of gambling, and providing punishment for the publication of obscene literature; laws to prevent the spread of contagious and infectious diseases; and also that higher and grander step, laws for compulsory education, thus compelling the elevation of the masses by undermining ignorance and superstition, the prolific sources of human misery and degradation. This is itself a wide field of inquiry; a field where Christianity and moral hygiene, social and medical science, and sanitary police, must join hands with education and law, to lift into social order the victims of evil and hereditary influences which they are powerless in themselves either to avoid or to conquer.

That mental activity is highly favorable to physical health and development, when systematically directed into useful channels, need hardly be argued in this day. Intellectual labor seems, as a rule, to contribute to longevity. It was formerly a sort of proverb, that "one of the rewards of philosophy is long life." The ancient philosophers, especially the Peripatetics, pursued their studies and imparted their instructions largely out of doors, amid the varied objects of nature. The amount of physical exercise taken in the open air was a remarkable feature in the life of antiquity, even among its scholars; and we have among them numerous examples of great longevity in men of intellect. Homer, Pythagoras, Plutarch, Thales, Galen, Xenophon, Carneades, Sophocles, Zeno, Hippocrates, Xenophanes, Democritus, and others, reached the age of ninety and upwards, while the majority of such men passed the limit of threescore and ten.

In the early days of this Republic, with simplicity and plain living, we find the same rule holding good. Chief Justice Marshall and Thomas Jefferson reached eighty-four; Benjamin Franklin and John Jay, eighty-five; James Madison, eighty-seven; and John Adams ninety-one. All these men certainly had not only vast intellectual labors to perform, but great burdens of care, anxiety, and responsibility to carry, and even serious privations to encounter; and we might greatly lengthen this list. Bearing on this point I have recently been informed by Governor Seymour, of New York, who has given great attention to the history and character of the North American Indians, that the more intelligent tribes were not only the dominant and conquering ones, but that they afterwards met the struggle with civilization more successfully than

those giving themselves up wholly to physical exercises; that they also maintained a higher physical and mental standard, and lived to a greater age; that these tribes, this day, number nearly as many as in the early history of this country; that they maintain their language, and largely their simplicity of life, in the midst of civilization.[1]

The ancient gymnasia, as well as the modern signification of the word gymnasium, bear witness to the sense of the importance of combining mental and physical culture. Mental culture is a powerful influence in developing the symmetry of the bodily organism, the tone and expression of the face, the organs of special sense, and the harmony of co-ordinating movements of the whole body. One can see this illustrated in our common schools at any time. The power of attention in the majority of young children, in any community, is not much aroused in ordinary life, and they often look dull and stupid on this account. These children enter school, and the direction of the attention to a few simple exercises, in common, awakens the power of attention; and soon, at the tap of a rule, the sound of a musical note, or the word of the teacher, the whole school instantly responds. Now, under such simple but common and systematic exercises and study, the whole expression of the school changes. The bodily organism soon conforms to the habit of attention and to the systematic mental training, and awkwardness and dulness are soon transformed into gracefulness, courtesy, and intelligence.

[1] Extract from Appendix to Address by Gov. Horatio Seymour, of New York, at the dedication of the Kirkland Monument, Clinton, N. Y., June 25, 1873.—The superiority of the Indians of New York, over those of adjoining States, is proved, not only by contemporaneous history, but by striking facts within our own observation. Their pride, heroism, and victories, through a long series of years, affected not only their mental and moral characters, but even their physical organizations. . . . . Beyond the evidences of their superiority to be found in history and science, we have living proofs of the vitality and vigor of the Iroquois. All others of the Indians, who once lived in the States lying east of the Mississippi, have been swept away, except a few who linger in the wild regions south of Lake Superior. None of them have withstood the power and influence of the whites, except the Iroquois. The Mohawks went to Canada, during the Revolutionary War, and most of the Oneidas removed to Wisconsin about forty years since. The other tribes still live in New York. In all their homes they are surrounded by the whites, and by high civilization, yet their numbers do not diminish at this time. For a while after the whites went among them, they fell off about one-third in population, but they now hold their number, with a slight increase in some cases. But the strength of their character is more strikingly shown by another fact. Although the Indians of New York, for three generations, have lived in the centres of civilization surrounded by a dense white population, with whom they are in constant contact, as their reservations are small, yet they retain their own language, their own customs, and about one-half hold their old religious faith; yet they have white teachers and preachers who live among them. In sermons or addresses, they must be spoken to in their own tongue, or through interpreters. At the celebration of the Kirkland Monument, a deputation of Oneidas was present. They belonged to a small remnant of their tribe, numbering less than one hundred and fifty, who did not go with their people to Wisconsin. They and their fathers and grandfathers always lived in the heart of New York, in the vicinity of large cities and villages. The tract of land they own contains but a few hundred acres, yet those present at Clinton, who were well-dressed men and women, could only speak to the assembly through an interpreter. In private conversation, with a few exceptions, they speak the English with hesitancy, as their thoughts are all conceived in the Indian language. The whole world is sending representatives of every lineage, language, and nationality to our country: all of these in a few years speak our tongue and adopt our customs, and in a little time are assimilated in all respects with our people. Even the most stubborn races of Asia yield to our phases of civilization. There is not in ethnology a more extraordinary fact than the resistance for more than a hundred years of our influences by this little band of natives. The continued existence of the Iroquois, while their kindred tribes have been swept away, and their resistance to our language and mode of thought, while all other lineages in our land have been assimilated, give proof of the vigor and marked peculiarities of their race.

Another common illustration is the change we mark in servants under the training of intelligent masters; under simple example and the stimulation of mind in the direction of systematic attention to duties, how quickly they are transformed, if they have any reasonable degree of capacity. The same may also be said of soldiers. Hume, in his Essay on National Character, says: "The human mind is of a very imitative nature; nor is it possible for any set of men to converse often together without acquiring a similitude of manners, and communicating to each other their vices as well as their virtues."

The great power of mental activity and attention, in modifying expression, bodily habits and movements, as well as general manners, may not only be seen in individuals and schools, but in whole communities and even nations. This is far more than imitation, it is substantial individual culture, the development of all the faculties in more or less symmetry. If we were asked the secret of the physical prowess and conquering power of the Roman people for a thousand years, we should answer it was the military education and discipline of the *whole* population from seventeen years of age, with its stern system of self-restraint and self-regulation. It was a civilization based upon the rigorous principles of the Lacedæmonians, rather than the lighter and more artistic life of Athens. The modern meaning of the word *virtue* was the *cause* of its Latin meaning, as confined to the behavior of men in battle, a stern temperance and self-control behind unflinching courage and endurance. It was once said by an American orator[1] that Rome was thrice mistress of the world, by her arms, her religion, and her law. It is in the last only that she retains supremacy, for there is hardly a civilized nation in which the maxims of Roman civil law do not form the basis of equity. And this is all the result of the primitive training of that great people both physical and mental. The same principle was illustrated in the Puritan Cromwell's troops, the soldiers of William the Conqueror, the German armies of Frederick William in the Franco-Prussian War, and conspicuously in the Revolutionary patriots of America and in their descendants, the soldiers on both sides of the contest in the recent war of Rebellion, in this country.

The more we examine into this question of mental hygiene, the more it seems to resolve itself, on the mental side, into a statement of the best methods of education and training to secure the highest and truest culture. And this is the line of thought which forces itself upon the mind as the true exposition of the words mental hygiene—a system of culture embracing all the interests of man in all his relations of life; education in its highest expression and broadest application; education to secure not simply a knowledge of man, and of nature and her laws, and the awakening of the faculties to a deep obedience which will make man reverence *her* in all *her* works and ways, or, in the beautiful language of Prof. Huxley, "the instruction of the intellect in the laws of nature, under which name I include not merely things and their forces, but men and their ways, and the fashioning of the affections and the will into an earnest and loving desire to move in harmony with these laws," adding "for me education means neither more nor less than this"—clear emphatic words of which no one can mistake the meaning: but far more than this, we should demand a broad and deep culture of man which would do all this, and which would also awaken in the soul a full conscious-

[1] Hon. Hugh S. Legaré, of South Carolina; N. Y. Review, 1841.

ness of its responsibility to One by whom all things exist; an education which would not only raise man to harmony with the laws of nature, but which would also raise him to obedience to the laws of God; which would make his life real, earnest, pure, and useful. To accomplish this, mental hygiene must include, therefore, not simply the mental and moral training in a general but also in a particular way; must as well include social restraints and duties, as I have heretofore indicated, and embrace a supreme regard for the welfare of the country—a true patriotism.

It is not out of place in this centenary year of the nation, to remind ourselves that this element of moral and religious restraint and discipline, this spirit of subjection to an overruling power above nature, was not left out of the practical life and training of its original founders. The first settlers of this continent began their conflict with wild nature, and still wilder savages, under a system of self-discipline and sense of religious responsibility, sterner even than that of the old Romans. It was indeed their *virtue* that brought them through successfully in their contest with the mightiest empire of Europe, and enabled them to lay the foundations of a governmental fabric which has been the astonishment and the study of European statesmen.

But to follow up the subject of mental hygiene in relation to individual life, it must be evident that I should have to enter into details not possible in such an address as this; I should have to take into consideration, not only the whole scope of what I have denominated, in a general way, educational means and influences, including domestic life, but also age, sex, civil condition, heredity, passions, the influence of climate, social customs, religion, etc., in all their varied relations as found in action in individuals, as also the questions of food, water, exercise, air, sleep, etc., all essential conditions and vital questions in the study of individual hygiene.

II. When we come to the question of mental hygiene in communities, we include all hygiene as to individual life, and at the same time enter the wide domain of sociology or social science. Here again we meet the great problems of education, social customs and laws, intermarriage, amusements, and indeed all the conditions of social and civil life, together with religious culture, which, though I have named it last, is really first and fundamental. In this age of books and thinking, no man can ignore this latter point if he would. While I have never been able to see any conflict between Science and Religion, certainly the tendencies of the times are rather to question closely their relations and their respective domains. Christianity has been challenged by science, in some quarters, and the old questions of faith, freewill, responsibility, necessity, etc., are again discussed in the light of increased physical knowledge and physiological investigations, and the more advanced views of psychology.

The literature of the age itself illustrates the subject of mental hygiene. Bulwer, in his "Caxtons," gives an admirable chapter on the hygiene of books. He suggests that reading should be governed by the mental state; that it should be suited to the morbid drift of thought, or the malady of the individual. As an illustration, he speaks of the folly of attempting to amuse a man in the midst of a great sorrow; and nothing could be more in accord with sound psychology. Referring to Goethe taking up the study of a science, after the death of his son, he says, "Ah! Goethe was a physician who knew what he was about. In a great grief like that you cannot tickle and divert the mind." He re-

commends for the sorrows of middle life and old age, "bringing the brain to act upon the heart." He would thus have philosophy lead and temper the emotions and the will, and enrich the true life by contemplating the lessons of experience. He says: "For that vice of the mind, which I will call sectarianism, not in the religious sense of the word, but little narrow prejudices that make you hate your next-door neighbor because he has his eggs roasted, when you have yours boiled, and gossiping and prying into people's affairs, and backbiting, and thinking heaven and earth are coming together if some broom touch a cobweb that you have let grow over the window-sill of your brains—what like a large and generous, mildly aperient dose of history! How it clears away all the fumes of the head . . . how your mind enlarges beyond that little feverish animosity to John Styles!" Here we have a strong hint, not only against the cultivation of a narrow range of thought, but also of the great value of that wide mental scope which takes in the interests of others, and occupies the mind in public and social interests and affairs of State.

Again he says: "I remember to have cured a disconsolate widower, who obstinately refused every medicament, by a strict course of geology. I dipped him deep into gneiss and mica-schist. Amidst the first strata, I suffered the watery action to expend itself upon cooling crystallized masses; and by the time I had got him into the tertiary period, amongst the transition chalks of Maestricht and the conchiferous marls of Gosan, he was ready for a new wife." But all men and women cannot grasp geology. No, but all can find, in morbid states, some serious mental occupation, if it be only their own sphere of labor, or some useful course of reading which will occupy them *out of themselves;* this is the secret, *out of themselves.* This would be substituting action for mere sentiment, a most important principle in mental culture. No lesson is more important than this, and it gives emphasis to what all experience teaches, that in the substantial realities of life are to be found the true sources of healthful mental discipline and growth; that while amusements are useful as recreation *after* toil and responsibility, they are not to be looked upon as the daily pabulum of the individual or of society; that, in excess, amusements become a kind of dissipation which creates a distaste for systematic and useful labor, and for the quiet of home life and its practical duties, and for all rational social intercourse. Thus real life grows tame and insipid; a constant, restless desire for excitement is substituted for the deep, solid stimulus of duty, of domestic responsibility, and of that substantial mental culture which alone can give to society strength and virtue.

Sentimentalism is a tendency of the age, and has a most important place, but it should not become so dominant in social life and in education as to exhaust the mental energy in trivialities, or in mere expression of the feelings, instead of leading it to action and duty. Mere sentimentalism, whether in social life, religion, or politics, demoralizes and emasculates all life and action; it is but a sensual indulgence at the expense of all vigor and energy in the practical advancement of the individual or of society. What the school of sentiment, as headed by Rousseau, did for France—the extravagances, the follies, and the fanaticisms to which it led—is patent enough from French history since the Revolution of 1789. By sentimentalism is here meant that exaltation of the feelings and sympathies of the mind which is always expending itself upon unworthy objects or causes, or in the mere contemplation of those

that are worthy; which Butler, in his Analogy, has pointed out with great psychological penetration, as mere emotional impulse, with no practical object, and no ontlet for reasonable action, and which is, therefore, always enervating and destructive to mental character.

This tendency is not found simply in the immense indulgence in novel-reading in these days; in the graphic and picturesque portrayal of crimes and social vices; in newspaper serials, which flood the country, and which are brought before people at every book-stand and in all the avenues of travel; in the publication, broadcast, of the minute details of crimes, suicides, and court trials, where sickly sentiment, and social vices, and the passions of mankind, become the staple and the snm; but this tendency is also seen in science and in much quasi-religious teaching, as well as in a multitude of so-called social and humanitarian schemes which promise to lift man into a realm of thought and feeling where he will necessarily, as by a law of his being, drift to the good. This spirit of sentimentalism and restless love of novelty is only a form of scepticism, and drifts into sensualism in morals, into useless and vague speculations in science, and into transcendentalism and infidelity in religion, and in all its tendencies leads to morbid, unhealthful, and impracticable mental action.

Carlyle has said that "the proper task of literature lies in the domain of Belief, within which, poetic fiction, as it is charitably named, will have to take a quite new figure, if allowed a settlement there," and that "the exceeding great multitude of novel writers and such like, must do one of two things, either retire into nurseries, and work for children, minors, and semi-fatuous persons, or sweep their whole novel-fabric into the dust cart, and betake them with such faculty as they have, to understand and record what is true, of which there is, and ever will be, a whole infinitude unknown to us;" and he adds, "poetry will more and more come to be understood as nothing but higher knowledge, and the only genuine Romance for grown persons, Reality."

Bulwer, with a sort of prophetic fore-glimpse over the field of these developing tendencies, speaks in the chapter already mentioned, of "curing a young scholar, at Cambridge, who was meant for the Church, when he suddenly caught a cold fit of free-thinking, with great shiverings, from wading out of his depth in Spinosa." He failed when he tried him on the divines, but succeeded by dosing him first with chapters of faith, in Abraham Tucker's book; then strong doses of Fichte; after these the Scotch metaphysicians; ending up with a plunge bath into certain German trancendentalists. He adds, "having convinced him that faith is not an unphilosophical state of mind, and that he might believe without compromising his understanding, for he was mightily conceited on that score, I threw in my divines, which he was now fit to digest, and his theological constitution since then has become so robust that he has eaten up two livings and a deanery." Now "wading out of his depth in Spinosa" is admirable. These youths are now grown quite numerous, and count among them some of the ablest scientists, who seem to be carried away by "winds" or by "doctrine" into what St. Paul styled, in his day, "science falsely so-called." They drift so far out as to get into what they call the "unknowable" and the "unthinkable," which phrases, if the veil of time was removed, would disclose underneath the inscription of the Athenian philosophers on a certain altar, noticed by St. Paul, as he entered that learned city eighteen hundred years ago.

If we look through the history of such mental drifting, we cannot but recognize it as productive of vast evil. Certainly such speculations have, as yet, made no scholar wiser or better, judging by what they have imparted to the world on the subjects of Christianity or Revelation. To be sure, we are aware that doubt has been even dignified as an essential condition of mind for the highest perception of Truth! Now the mental hygiene suggested by Bulwer was as admirable as his diagnosis. He did not strand his patient, at the start, by discussion and dialectics, but led him by a line of thought, natural to the patient, through the regions of apparent contradictions and doubt, according to his powers of mental digestion, and finally cultured him to the full truth, and at length made a Dean of him, where he had the widest scope for faith and works, as well as a field for mental action in the highest range of human duty.

A most notable instance of this "wading out" is the case of a late President of the British Association. A brilliant man, with rare powers of analysis of physical facts and phenomena, his mind trained in this direction, he launches out on the track of the great spiritual ocean, to which he applies his physical tests, and fails. He is followed instantly by another brilliant mind in physical science, who takes down his system of astronomy to follow the wake of a new leader. These are conspicuous cases, and in other times the former might have become the founder of a sect; but instead of that, his structure falls to pieces as he contemplates it. Besides, he confesses that he has *moods*, which is equivalent to unsoundness, when moods are confessed in explanation of statements and opinions. This is encouraging, for it shows that the great and constantly increasing body of truth, extended in all directions, is not only unmoved by scepticism, but is gradually undermining it by explaining the phenomena on which it rests for the title of its existence, and is also revealing principles so much mightier and broader than man's theories of Nature and of God, that Scepticism dies in the light of Truth.

Newton, after reaching far into the arcana of nature, and finding his vast knowledge so little of the whole that he compared it to a few pebbles on the shore of the ocean, is the modest but grand symbol of true progress. He illustrates the majesty of science, and her respectful homage at the feet of the Creator. That science which is "puffed up," and which stands ready to unveil the sanctuary, and to enter into the holy of holies and reveal the Almighty to man by chemistry and telescope, and thus find out the secret of his creation and existence, and discover the government of the moral world in a series of correlated forces, is not the science of religion which can captivate the world of to-day. However man may move in a cycle of the same truths and deceptions, in kaleidoscopic variation from age to age, God is unchangeable, and has declared Himself to be "past finding out."

So principles are eternal, though our methods change. The ideas of God, in ancient philosophy, which Pythagoras and Socrates, Plato and Cicero, saw dimly through the body of science and truth then developed, cannot, at this day, be accepted as religion, though their faith and loyalty to an invisible Creative power stand unquestioned, and like a rock in the desert of centuries. Though Plato is perhaps the grandest figure standing forth in the history of human mind, his theories are but as the dawning light to the mid-day sun, in the abstract truths, developed science, and revelation of to-day. Much less can we accept Democritus and his followers. When Horace sang of the "*Integer vitæ, scelerisque purus*," he but struck a glimpse of the same truth which belongs to the

province of religious culture, and which had long before been uttered by the Royal Psalmist, "Blessed is the man who hath not walked in the counsel of the ungodly, nor stood in the way of sinners, nor sat in the seat of the scornful, but his delight is in the law of the Lord." The psalm of Horace and the psalm of David are alike devout confessions of the blessedness of purity, and are tributes to the importance of moral culture as an essential to the full development of mind and mental balance.

Indeed, without this moral culture, we may say, it is well nigh impossible to understand even Nature herself. Certainly this is so, as far as the ideas of purpose and design are concerned. As Baring Gould has well put it, the world is a visible exhibition of the ideas of God, a mighty book to be read. But who is to spell out this Created speech and comprehend its significance? Those who are to catch and understand the ideas of God, must have a spiritual nature capable of perceiving such truths. "Therefore, he who is to read Creation, must be neither mere spirit nor mere body, but must have a spiritual nature combined with a corporeal nature, so that, through the things revealed to the mind by the bodily senses, the thoughts of God may be perceived." Mental hygiene or culture, from this standpoint, recognizes the essential nature of man as a spiritual being, and points to the necessity of educating his moral nature in harmony with his intellectual, to bring forth the full man.

In this view the very wastes and solitudes of nature come to have their moral and spiritual uses. In a burst of enthusiasm, Baring Gould exclaims: "The time of Alpine snow has come; age after age has seen it powdered on the mountain peaks, slide down the flanks in ice, and flow away in rivers to the sea, unesteemed save for the water it yielded. But its time has come, its value is known. There is no medicine to a weary brain, like the golden light on a distant bank of Alpine snow. . . . I remember a mountain scramble, leading me suddenly, from rough rocks and sear grass, upon a dell of rich greensward girt about with pines. Set in the turf was here and there a fallen star—a yellow anemone; on the rocks the carmine Alpine rhododendron was in full blaze of blossom, and over all the sward was a tender bloom of forget-me-not. Over head *burnt* a glacier in the summer sun, and a thread of silver fell in powder from it, waving in the soft air. I am not ashamed to tell you that that vision filled my heart to overflowing. God spake through that scene, through every flower, out of the mountain, out of the ice. The voice of God, walking in that garden, was as audible as of old in Paradise, when Adam heard it in the cool of the day."

No reflecting man can fail to see that the attention given to education, all over the world, is a most significant fact in the history of this period. That education, in some degree, shall be universal, seems to be a common sentiment. That this is essential to the progress of civilization, needs only to be stated. The great questions that arise are, what shall education be, and what shall it include? Shall it include religious instruction in all fundamental training? is the real problem, however the question may be stated. And reaching higher in the scale, the same great question intrudes itself only in a different form. The scientific theory of culture, set forth by the school of which Professors Huxley and Tyndall are exponents, as Principal Shairp has so well pointed out, gives little account of and makes no provision for the moral elements of human nature, and this would seem to be its deep defect. As he truly says, "the knowledge of the highest things, those which most deeply concern

us, is not attained by mere intellect, but by the harmonious action of understanding, imagination, feeling, conscience, will—that is, of the whole man—reason in its highest exercise, intelligence raised to its highest power." And this for the single reason that no science can call our *whole* nature into play at once. This can only be done by religion, which alone calls upon the whole of man. When Prof. Huxley presents life as a game of chess, with an invisible player, he endeavors to save the idea that a man *must* respect the rights of others; but there is no more room for such an idea in his scheme than there is in a shipwreck, or in Darwin's doctrine of the survival of the fittest. It is *not* a *natural* impulse of man to respect the rights of others, or "to love one's neighbor as one's self;" as Principal Shairp has well said, it requires the whole weight of Christian motive to do either.

III. When we come to examine mental hygiene from a national point of view, we see that it comprises all that gives intelligence, character, dignity, progress, and stability to national life. In this greater field the lesser are included. That hygiene which tends to elevate a people, both mentally and physically, by a true and rational culture, is in fact mental, moral, and physical training, resting on definite principles, and these so accepted as to become the prevailing and growing habit of the people; or, in other words, culture extending itself into national habits, thoughts, and pursuits. Whatever theories we may adopt as to the equality of man, the best practical result of national training must be to give to each class of minds that bias which will serve to develop useful individual tendencies, and at the same time, in the main, correspond with its social status. For whatever general education or fundamental culture we may rest upon as a prescribed system for general application, the professional man, the merchant and business man, the mechanic, the farmer, the clerk, and the laboring man, need different training to fit them for practical life. The question of mental hygiene is therefore not simply how we may best train men so as to cultivate mental health and physical vigor, but also how we are to bring about the use and application of all the principles and agencies which are best adapted to develop, expand, and maintain in balance the mental and spiritual life of individuals, communities, and nations, so as to insure progress in civilization, a healthy state of general and domestic morals, and, at the same time, the advancement of culture, arts, and industries.

It is only within a comparatively short period, that the study of general and mental hygiene has been demanded, under the progress of science. This study has been stimulated by the developing necessities of civilization, the greater attention to sociology, and the progressive ideas of personal liberty and responsibility. All the ancient civilizations were but little concerned in the welfare of the individual, as a unit going to make up national life. Knowledge and the exercise of governmental functions were confined to the few. The great masses were only so much brute force, or mere physical elements, in the hands of rulers and leaders, to carry out their own ends; and to all this the masses gave almost absolute assent. The lives of the people were held cheap by the rulers, as well as by the people themselves. Even the great revolutions, from time to time, were not movements of the people, but were simply brought about by kindred though antagonistic governing families, and the people were used in their respective interests, being aroused under the temporary stimulation of the passions of the hour. They had no appreciation of the ultimate tendencies of public movements, and no hope or desire

for personal elevation or advancement. In such a state of national life, mental culture could have no wide significance, and no place except among the learned, as a mere subject of contemplation. Therefore for many ages we have little on the subject of mental hygiene, in any direction, beyond the philosophic declarations and fables of learned men. The priestly orders, indeed, in ancient times combined and exercised largely the professions of minister, teacher, and physician, and were also the trusted advisers of kings. The Mosaic law laid down the rules of hygiene, as it did those of morals, intermarriage, and worship, in a single code.

The aphorisms of Hippocrates embrace about all that is valuable in medical literature of the pre-Christian centuries. The Code of Health of the School of Salernum, for hundreds of years a medical classic, contains the recorded knowledge on the subject of health down to the sixteenth century. A recent translator, Prof. John Ordronaux, says of it, "it was for ages the Medical Bible of all Western Europe, and held undisputed sway over the teachings of its schools, next to the writings of Hippocrates and Galen." It contains a great many precepts and dietetic rules, but deals little with mental hygiene; and this is the sum:—

"Salerno's School, in conclave high, unites
To counsel England's King, and thus indites:

If thou to health and vigor wouldst attain,
Shun weighty cares—all anger deem profane,
From heavy suppers and much wine abstain.
Nor trivial count it, after pompous fare,
To rise from table and to take the air.
Shun idle, noon-day slumber, nor delay
The urgent calls of Nature to obey.
These rules, if thou wilt follow to the end,
Thy life to greater length thou mayest extend.

Shouldst Doctors need? be this in Doctors' stead—
Rest, cheerfulness, and table thinly-spread."

The author closes with a valedictory which would indicate that he felt he had accomplished a great work:—

"The Flower of Physic endeth here its strain;
The Author, happy o'er his garnered grain,
Prays that in Heaven there be prepared for him
A seat near Christ, and His blest Seraphim.
Amen!"

We must not forget, however, the great services rendered, during the dark ages, to Science and Literature by the Monks and Religieux while buried in their cloisters, as well as their work in preserving the treasures of learning from the all-surrounding devastation. It is admitted by all historians that, in days of violence and anarchy, the Church was a defence and refuge of the poor and the oppressed, as well as of the learned, against the hand of tyranny and rapacity. To the Benedictine orders, at least in their constant and systematic attention to the cultivation of the soil, and the implements and improvements of agriculture, we owe a great lesson of that primitive truth, that in the sweat of man's face shall he eat bread. It may even be said that the motto of this order, *laborare est orare*, has become the watchword of modern civilization, for in no period of the world has labor been so dignified as in these times, and the machinery of labor so multiplied for the uses of man.

Mental hygiene, from a national point of view, would also cultivate in the people a harmonious and universal aim towards elevated and yet practical ideas. A national sentiment, fostered and dignified by government, in favor of education, mechanics, agriculture, arts, becomes a most powerful mental stimulant to individual effort, and seems to give breadth, tone, and vigor to national mind and character. No people, perhaps, ever gave more earnest and practical attention to educational power and the value of morality, as elements in government, than the Puritan stock of New England. From the first, the church and the school-house rose side by side, and whatever economy and frugality they exercised in affairs, and they were marvels in these virtues, they never stinted the head and the heart. They had lofty ideals, and they practised stern virtues, and when national oppression came they had stout hearts, willing hands, and clear heads, to offer in the struggle for liberty and the founding of a nation. The sentiments of Union and Liberty, early and deeply rooted in the mental soil of the early inhabitants of the American Republic, have propagated their influences and spread their roots and fibres through the blood-soil of children's children, and we see the result in millions of active intelligent minds, carrying forward with united and persistent purpose the vast interests of this great nation, and subduing this mighty continent, in its multiplied physical resources, to the utilities of mankind, as though governed by a single national impulse.

The founders of the Republic, in every part of the land, seemed to have been thoroughly permeated with the spirit of personal and public duty. With them, Liberty meant Law and obedience to principles of Justice—an obedience, as beautifully expressed by Ruskin, "chastisement of the passions, discipline of the intellect, subjection of the will, fear of inflicting and shame of committing a wrong; respect for all who are in authority, consideration for all who are in dependence; veneration for the good, mercy to the evil, sympathy with the weak; watchfulness over all thoughts, temperance in all pleasures, and perseverance in all toils."

Had our ancestors cultivated the softer graces, and given themselves up to games, sports, and ease of life, and the government contented itself with hereditary dignities, leaving the mass of the people in ignorance, and to think and act only in the narrow sphere of providing daily bread by daily toil, how different would have been the mental status of this nation to-day! If, on the other hand, the inhabitants of this country should ever become so demoralized and degraded as to find their contentment, like the people in the latter ages of Rome, in material comforts alone—*panem et circenses*—mere bread and amusements—then, too, like the later Romans, they would soon become the prey of family feuds and contending factions, ending in the despotism of a swift succession of flagitious rulers, till the whole political system would sink into final disintegration and ruin.

This Centennial, a part of the movement of which this International Medical Congress represents, is a great national thought, and a most powerful influence in stimulating national mind, as well as individual, in the direction of healthful mental activity. Indeed, it is itself a vast and far-reaching means of culture, which touches a responsive chord in nationalties of the most diverse social and political character, but nevertheless in harmony in the one direction of progress. To impress men by such magnificent displays of wealth, mechanism, and art; to show them

that life is more than meat and drink; that a nation is great and powerful in proportion as its citizens are cultured to refinement, utility, morality, and personal responsibility; that these constitute the foundation stones of national greatness and prosperity, is in itself a great national hygienic measure. As the accumulation of patrimonial treasures, learning, and office, give dignity to families, and stimulate to higher culture, so the accumulation of treasures of all kinds, and the recognition and cultivation of art and learning by nations, tend to dignify national reputation, and to stimulate citizens of all classes to higher efforts and more patriotic lives.

Thus a nation secures mental and moral growth and breadth of enterprise. No one can look at the wonderful Exposition, now held in this city, without realizing this fact. The world seems, indeed, to be here assembled. The Egyptian, the oldest civilization, stands before us today as it stood in the days of the Pharaohs. The march of progress and the attrition of nations may have modified her national life in some outward things, but the central ideas remain the same; her escutcheon is unchanged, and she sends to this Centennial, as an essential treasure, the head of Rameses, thus typifying her original and perpetual dignity, unbroken through the long tide and flow of centuries. And so down through the roll-call of nations, to our own, each has its own grand representative idea. At the end of a hundred years we stand at the statue of Washington, and relate his virtues, as embodying the central ideas out of which grew, and on which rests, the deep, broad, and sure foundation of this Republic. Egypt may come to us; she may take our ploughs and reapers, our engines and printing presses; but she will only enthrone Washington when she accepts our ideas.

The true greatness and dignity of any nation will always be measured by the standard of its mental and moral culture, not simply by the intellectual standard it presents in its military power, its science and arts, and its dynamic forces, but also by its will and capacity for morally elevating its citizens, without clash of caste; maintaining universal freedom, with all men equal before the law. The present Emperor of Russia, realizing such a sentiment as essential to the dignity, prosperity, and permanence of the government, transformed, in a day, millions of serfs into freemen, the grandest ukase in the history of time. This is the substance of Magna Charta, the glory of England. This was the ostensible aim of Cæsar. His memory is quite as much dependent on his philosophic culture, and his assimilation to the people, as on his conquests. He shed lustre on Rome, and on mankind, by his amazing combination of simplicity, learning and statesmanship, with the greatest capabilities of a soldier, all of which he illustrated in the midst of a galaxy of the most magnificent minds in the annals of the world. His name fitly represents the power of mental culture in the direction of definite ideas, in a ruler looking to the elevation of a people as the true source of national power.

Rome lost in prestige when she accustomed her people to ideas of conquest and personal ease, above moral culture, in its wide meaning. Indeed, no nation has ever maintained permanent elevation and power, which has encouraged or permitted public opinion to act outside of the pre-ordained boundaries of religious truth. The belief in a God must be the corner-stone on which a nation rests. Both Greece and Rome flourished in power, arts, and arms, so long as they clung to a belief in a supreme Providence, above Nature. But when the speculative

philosophy of Epicurus and Lucretius, with its absorbing sensualism, usurped the ancient worship, they perished beneath the blight of a cold scepticism. The glory of Egypt was clouded with Cleopatra, who represented deified sensuality on the throne of a Nation. The great Assyrian Empire, in like manner, fell under Sardanapalus, the gilded monarch of Asiatic licentiousness. France well nigh perished when she installed the Goddess of Reason in the seat of Worship, and her Chief Assembly voted Death to be an Eternal Sleep.

Under the cultivation of the ideas, and the practice of the principles, to which I have referred, by the founders of this Republic, we have the national fruit, not only in a great and well-established nation, but conspicuously in the wonderful development of the resources of high civilization all over this continent. It is a truth, well worthy to bear in mind always, that education, with them, embraced ideas of religious freedom, which were cultivated together, no matter what the calling in life. And it is not too much to say that in the rigid spirit of utility and the high sense of responsibility of the early fathers, we have the seed from which has germinated, over this broad land, the personal independence of character, the inventive genius, the subjection to law, and the matchless energy, which have made us equal in power to the older nations of the world, which have also given us an individual national character—stamped us as Americans—notwithstanding that we represent all the nationalities of Europe; which have developed a national mental hygiene which reduces and conforms the cosmopolitan ideas of the vast and constant drift to our shores, to the national standard, which prevents anything antagonistic to the fundamental principles of the government from taking root, and which assimilates and harmonizes all the seeming antagonisms to the genius and spirit of the constitution, the moment they are subjected to its dominating idea, "government of the people, by the people, for the people."

I might properly allude to the great influence exerted on the national mind by such men as Franklin, Rush, William Penn, Robert Morris, Richard Henry Lee, John Jay, the Adamses, Hamilton, Jefferson, Madison, and others, if there were time; but such influence, however special and potent, was, after all, only the projection and happy presentation of principles which, when thoroughly impressed, acted on the mind of the people in moulding national thought. The work of these men was done through the reason and judgment, and not by popular display and glamour, and it was abiding. Economics and population, education, statesmanship, finance, constitutional law, Political Economy in all its wide bearings, received from them the most earnest and profound discussion. However great their attention to religion, they did not confound it with state morals; but, on the one hand, they maintained Christianity and the highest responsibility to God, and, on the other, they sought to work out, under laws, the mutual rights and relations of men under their new social and political conditions of government.

Their lives were illustrations of the principles they advocated; William Penn exercised a wide and mighty influence in securing not only the mutual co-operation of savages, but also of classes of men bred in other traditions, and in bringing all to the formation of national habits and character. Yet he represented no victor with temporary plaudits, no sensational or dramatic phase of social life or regeneration. His power illustrates what education, aided by elevation of character and equi-

librium of the intellectual life and passions, may do in a man who is controlled by truth and directed by spiritual light. Wilberforce, in England, illustrated the same great influence on national mind. He showed how a strong mind, panoplied in its convictions of universal justice, might gradually undermine historic precedents, against all the forces of conservatism arrayed in opposition, as well as against the apparent interests of the nation. Slavery was then a part of the national wealth, but it died through the influence of this one peaceful mind, breathing condemnation upon it, and this in the very presence of those whose material relations to it were of the closest character. Thus a whole nation was transformed by a mental revolution, wrought solely in the name of universal philanthropy, justice, freedom, and religion.

Such are some of the higher triumphs of national culture, when it embraces the moral and spiritual elements of Christianity. Though this age may be characterized as one of liberal tendencies of thought, in all directions, it has been permeated by the principles of Christianity, and to-day there is more respect for religious truth, and a firmer belief in the necessity, for both man and nations, of faith in a God, than when the century commenced. When, in the recent French Revolution, the Archbishop of Paris, Monsiegneur Darboy, was struck down by the Commune, the nation turned from the act with horror. Yet the Bishop was only a man, and one among the hundreds of noble men who thus perished. But he represented Religion, and millions of people, alike Protestant and Catholic, condemned the deed as one of infamy, and as a diabolical defiance of the very instincts of humanity, as well as of the traditional sentiment of Christendom.

The lesson of mental hygiene, for nations, which we learn from all example, is, not that education and wealth, nor the refining influences of æsthetic art, will suffice for the highest development of national mind, but that, if underneath and through all these are not interwoven the great truths of moral responsibility to the author and upholder of all governments, lifting man above the dominion of the baser passions, the nation dies as an individual dies; for "unless the Lord build the house, they labor in vain who build it."

In the Convention at Philadelphia, in 1787, for forming a constitution for the United States, after some weeks had passed in fruitless debate, a proposition having been made for daily prayers, Dr. Franklin rose and said: "In the beginning of the contest with Britain, when we were sensible of danger, we had daily prayers in this room for Divine protection. Our prayers were heard and graciously answered. All of us who were engaged in the struggle must have observed frequent instances of a superintending Providence in our favor. To that kind Providence we owe this happy opportunity of consulting in peace on the means of establishing our future national felicity. And have we forgotten this powerful friend; or do we no longer need His assistance? I have lived a long time, and the longer I live the more convincing proof I see of this truth, that God governs in the affairs of men. And if a sparrow cannot fall to the ground without His notice, is it probable that an empire can rise without His aid? We have been assured in the sacred writings that, except the Lord build the house, they labor in vain that build it. I firmly believe this, and I also believe that without His concurring aid we shall succeed no better, in this political building, than did the builders of Babel."[1] The motion was carried.

[1] Debates on the Constitution.

This illustrates the sentiment and temper of those who founded this nation, and may we not say, standing where we do, that the influence of this illustrious example has had some share in determining the tone and the practice, in that respect, of this renowned University from its foundation, whose successive Provosts have been eminent examples of the essential harmony between the different qualities of Faith and Science? These latter thoughts have come into my mind since entering this hall, while looking round upon the long line of Reverend Provosts speaking out from the canvas, and then reading over the door of entrance the grand inscription, "In Honorem Dei." An institution, like a State, which writes over its portals, "in honor of God," cannot fail of success and power, before the people, as more than a century has here demonstrated. And this is my Alma Mater.

For individuals and communities, the quaint lines of George Herbert, with which I close this Address, are a suggestive and pregnant summary:—

Slight those who say amidst their sickly healths,
Thou livest by rule. What doth not so but man?
Houses are built by rule, and Commonwealths.
Entice the trusty sun, if that you can,
From his ecliptic line; beckon the sky.
Who lives by rule then, keeps good company.

Who keeps no guard upon himself, is slack,
And rots to nothing at the next great thaw.
Man is a shop of rules, a well-trussed pack,
Whose every parcel underwrites a law.
Lose not thyself, nor give thy humors way;
God gave them to thee under lock and key.

ADDRESS ON AMERICAN MEDICAL LITERATURE.

BY

LUNSFORD PITTS YANDELL, M.D.,

OF LOUISVILLE, KENTUCKY.

I HAVE attempted in this Address to give some account of the books which have been written by the physicians of the new world, since the settlement of America by white men. The history embraces a period of nearly two hundred years, and includes the names of as many authors, and the titles of more than as many publications. Restricted as I am, both in space and time, my notices are necessarily brief. As to most of them, they are nothing more, indeed, than a catalogue of names and titles. But it occurred to me that I could not in any other way so well meet the wants of the profession in an address like this, as by presenting a full list of our medical works in the order in which they have appeared, so that we may see, and that those who shall come after us may learn, what the medical men of America have done in the first century of our national existence. My references are confined almost exclusively to books, but occasionally I have noticed pamphlets and articles in Transactions of Societies, which appeared to me to possess unusual value. To do justice to the medical literature of America, would require something more than a single discourse. All that is proposed in this, is to give an outline of the subject; and, with all the pains I have taken to make my list complete, I can hardly hope that it will not be found chargeable with many omissions.

The Literature of Medicine had acquired but little extension, and was still expanding slowly in Great Britain, when the first emigrants for America left her shores. Harvey was just then announcing his grand discovery of the circulation of the blood. Sydenham had not been born, and it was half a century afterward that his works, conceived in the true spirit of the Baconian philosophy, and the standing glory of English medical literature, made their appearance to put a new countenance upon the Science of Medicine. Mead and Cheselden were born more than half a century afterward. The writings of the Hunters, and of Cullen, appeared only as the Colonies were ready to set up in the world for themselves; and the discoveries in chemistry which imparted to it the character of a science, were made by Black and Priestley on the eve of our great political revolution.

It is not surprising, then, that hardly anything was accomplished in the way of authorship by the physicians of the Colonies during the first century of their settlement. For fifty years nothing at all was published by them, of which we have any record. The first essay came out in 1677, bearing the title "A Brief Guide in the Smallpox and Measles." It was published in the province of Massachusetts, thirty years before the first newspaper was issued in America, and more than forty years before one was established in Philadelphia. Its author, Dr. Thomas Thacher, as

was not uncommon in the new settlements at that day, united in his person the two professions of divine and practitioner of medicine. He was the first minister of the Old South Church, in Boston, and was accounted "a great divine" as well as "a learned physician," who, preaching and practising "to general approbation" as long as he lived, had his name worthily perpetuated in the *Magnalia* of the famous Cotton Mather. His unpretending essay, composed especially for the instruction of the people, seems to have remained more than half a century without a successor. It was not until 1720 that the next tract relating to medicine appeared. Dr. Cadwallader Colden, in that year, published an account of the climate and diseases of New York, founded on his own observations and experience; and from that time medical publications followed in quicker succession.

Three essays respecting inoculation for smallpox were published within a few years of each other, by three Boston physicians. Dr. Nathaniel Williams, one of the three, was, like Thacher, both physician and preacher; another was Dr. Benjamin Colman; and the third was the celebrated Zabdiel Boylston, who was the first physician to make trial of the hazardous practice in the new world, and who narrowly escaped falling a martyr to it. Pharmacy and the Medical Botany of the new territory, attracted the attention of its physicians at an early day; and treatises on the preparation of drugs, the polygala senega, and the great water dock, were written by Dr. Howard, Dr. Tennent, and Dr. Colden. Dr. John Clayton, of Virginia, produced, in 1743, a *Flora Virginica*, so highly esteemed that an edition of his work was issued some years afterward in Leyden. An essay on fevers was written by Dr. Walton in 1732; one on scarlatina, by Dr. Douglas in 1736; one on the iliac passion, by Dr. Cadwalader in 1740; and one on yellow fever, and a second on the causes of the variety of colors in people of different climates, by Dr. John Mitchell in 1743. Dr. Lining also wrote an account of yellow fever, in which he started the idea, never before advanced, that persons who have suffered with the fever are not subject to a second attack.

Douglas, in his paper, was the first to recommend calomel in scarlet fever. Cadwalader had the good sense to condemn the use of quicksilver and drastic purgatives in lead colic, which he described as the "iliac passion," and advised opiates as preparatory remedies in that affection. The letters of Mitchell on yellow fever are of peculiar interest, as having led to the heroic practice in the disease for which Dr. Rush was noted at a subsequent day. Dr. Chalmers, of South Carolina, published a paper on tetanus in 1754. Dr. Bond, of Philadelphia, published, in 1759, an essay on the use of bark in scrofula; and in 1760 Dr. John Bard, of New York, made public the facts in a case of extra-uterine fœtation which had come under his notice. Dr. Bard, the same year, also published a valuable essay on the nature and causes of "Malignant Pleurisy," as it prevailed on Long Island in the winter of 1749, a disease since recognized in the epidemics of typhoid pneumonia which have more than once swept over our continent. In 1769 some letters on malignant sore throat were published by Dr. Ogden, of New York; and Dr. Kearsly, of the same place, sent the same year a paper to the Gentleman's Magazine, at London, on angina maligna. The thesis of Dr. John Moultrie, of Charleston, the first graduate in medicine from South Carolina at Edinburgh, was printed in 1749. It described yellow fever as he had seen it in his native city. The theses of Morgan, Shippen, Kuhn, Rush, Bard, Kissam, and other American students, were printed at Edinburgh from 1749 to 1776.

Some of these essays, treating of the diseases incident to the new world, deserve to be rescued from the oblivion that has overtaken them, and if collected would form a volume acceptable to the profession. But it is to be remarked that they were all issued in a fugitive form; many of them treated of subjects the interest of which has long since passed away; most of them were brief papers, such as would now make articles in our medical journals, and nearly all are now wholly inaccessible. At most, they can be regarded as nothing more than an introduction to the medical literature which in the course of the century succeeding them has become so voluminous.

The medical literature of America may with truth be said to have commenced with the century whose years we have just numbered. Just as it was about to open, Dr. John Jones, of New York, foreseeing the need of surgical knowledge likely soon to arise, prepared, in the autumn of 1775, and in anticipation of the impending struggle, a little volume on wounds and fractures. It is the first, in time, of American works on surgery. Its claims to merit were small, if regarded as an original work, since it was little more than a compilation; but the compiler was a surgeon familiar with the art about which he was writing, and his volume proved highly serviceable to our inexperienced and young surgeons during the war. In 1776, an able work was published in two volumes, on the Climate and Diseases of South Carolina, by Dr. Lionel Chalmers, of Charleston.

But ten years before this time, an event occurred which marks an epoch in the medical history of the country. I refer to the creation of a public school of medicine. This, more than any other movement recorded in our history, has shaped our medical literature and contributed to its growth and development. The school was inaugurated under circumstances that invest it with uncommon interest. The address delivered on the occasion was published, and is extant in our libraries. Among the Trustees of the College, who weighed the arguments urged for the erection in it of a Medical Department, was Benjamin Franklin, President of the Board. Dr. John Morgan and Dr. William Shippen, its founders and earliest professors, were medical scholars such as might rightfully aspire to lay the foundations of medical education in a new empire. They had prepared themselves for teaching by long and laborious study. An imposing assemblage of the citizens of Philadelphia was present to witness the commencement in their college, and to hear Dr. Morgan's address on the institution of medical schools in America.

"It is now," he said, "more than fifteen years since I began the study of medicine, and I have arrived at the middle age of life endeavoring to lay up treasures of knowledge." And he continued, in words that proved prophetic, "Perhaps this medical institution, the first of its kind in America, though small in its beginning, may receive constant increase of strength, and annually exert new vigor. It may collect a number of young persons of more than ordinary abilities, and so improve their knowledge as to spread its reputation to distant parts. By sending those abroad duly qualified, it may give birth to other institutions of a similar nature calculated to spread the light of knowledge through the whole American continent wherever inhabited."

In the great concourse of "respectable citizens" gathered to hear this discourse, was a young student of medicine who was destined to become not only the great luminary of the school, but the foremost of American medical teachers and writers. Benjamin Rush had been for three years

a student under Dr. John Redman, in Philadelphia, translating Hippocrates, and making memoranda on yellow fever and other current epidemics of the time. Three years later he was admitted to the degree of Doctor of Medicine in the University of Edinburgh, having defended a thesis *De Concoctione Ciborum in Ventriculo.* Returning home he was elected, in August, 1769, when under twenty-four years of age, Professor of Chemistry in the Philadelphia Medical College, now the University of Pennsylvania.

With Rush, to teach was to write. The motto on which he was in the habit of insisting most strongly to his pupils was, *legere sine calamo est somnere;* and he studied his profession with pen in hand, recording observations which are still of value to writers on yellow fever. The year after his election he appeared before the public as author of what he styled "Sermons" to young men on temperance and health. Three years later he was invited to deliver the annual oration before the American Philosophical Society, of which Franklin and Jefferson were members. He chose as his subject "The Natural History of Medicine among the Indians of North America, and a comparative view of their diseases and remedies with those of Civilized Nations." This oration makes the first paper in his "Inquiries," the first volume of which was issued in 1788. No one can read it without a feeling of profound respect for the talents and scholarship of its author. It is philosophical in tone, rich in original observations, and written in a simple, graceful style. The volume to which it forms the introduction raised its author at once to a position among the leading medical writers of the time. Of the other papers in the volume, one is devoted to pulmonary consumption, and it is interesting to remark that in his treatment of that disease Dr. Rush anticipates the therapeutics of the present day. He gives a graphic description of "breakbone fever," in which he was the first to note the unwonted depression of spirits which attends the disorder. For scarlet fever, on which he has a chapter, he thought that he had found a specific in calomel, which he believed to be as sure a remedy for croup, also, as bark is for intermittent fever.

A second volume of "Inquiries" followed on the 4th of July, 1793. Another oration before the American Philosophical Society forms the first paper in this volume. Its subject is "The Influence of Physical Causes on the Moral Faculties." The titles of his orations indicate the decided turn of his mind to philosophical disquisitions; the matter composing them proves how closely and widely he had observed, and how profoundly he had reflected on, the subjects of discussion. A second paper of great interest in this volume is an inquiry into the causes of the increase of bilious and intermittent fevers in Pennsylvania. A third relates to pulmonary consumption, to which he returns in his second volume to insist, with greater emphasis, on the utility of iron, cold baths, and horseback exercise, in the early stage of the disease. Another chapter is given to an inquiry into the state of the body and mind in old age, with observations on its diseases and their remedies. It is, perhaps, the best in the volume. It is a charming article, and will compare most favorably with any essay on the subject to be found in any literature.

Dr. Rush's third volume was issued in 1794, and is taken up with a history of the yellow fever, which ravaged Philadelphia the year before. It will be read, it is safe to say, while yellow fever continues to scourge the human race. No more graphic account of a pestilence was ever

written by a medical man. It possesses all the charm of a personal narrative. The author reveals the state of his feelings under the varying aspects of the epidemic. "Heaven alone," he says, "bore witness to the anguish of my soul in this awful situation," baffled in every attempt to stop the ravages of the disease. And when, after reading the manuscript account of the fever by Dr. Mitchell, he became successful, he says: "Never before did I experience such sublime joy as I now felt in contemplating the success of my remedies. It repaid me for the toils and studies of my life. The conquest of this formidable disease was not the effect of accident, nor of the application of a single remedy; but it was the triumph of a principle in medicine. The reader will not wonder at this joyful state of my mind when I add a short extract from my notebook, dated the 10th of September: 'Thank God, out of a hundred patients whom I have visited or prescribed for this day, I have lost none.'"

The principle by which Dr. Rush was conducted to these happy results, was that the debility attending this malignant fever is apparent merely—an *indirect* debility—in which the abstraction of blood and evacuation by purgatives tend to raise the pulse and increase the strength of the patient. His practice consequently was to bleed again and again, and give calomel and jalap in active doses, reducing heat by cold water. Finding the dose of ten grains of each drug too slow in its operation, he increased the quantity of jalap to fifteen grains. But the pleasure derived from his great triumph was attended by a serious drawback; his practice was denounced in unmeasured and bitter terms by many of his professional brethren. The effect of this was to excite such a prejudice in the public mind against his mode of treatment that he found it difficult to carry it out. Two of his colleagues, Kuhn and Wistar, united in its condemnation. Currie, a practitioner and writer of note and influence, declared in the public prints of Philadelphia that it "could not fail of being certain death." The report was started by some enemy that Dr. Rush was insane, and he relates that one of his former patients, a lady, "who had believed the report, expressed her surprise at perceiving no deviation from his ordinary manner in a sick room." It was even proposed by some of his excited fellow citizens to "drum him out of the city."

The terms in which Dr. Rush referred to the conduct of his enemies, under these trying circumstances, are worthy to be reproduced in this narrative, as illustrating the magnanimity of his nature. He says: "I allude to these slanders now only for the sake of declaring, in this public manner, that I most heartily forgive them; and that if I discovered at any time an undue sense of their unkindness and cruelty, it was not because I felt myself injured by them, but because I was sure they would irreparably injure my fellow citizens, by lessening their confidence in the only remedies that I believed to be effectual in the reigning epidemic. I commit the calumnies which have followed my opinions and practices in this fever to the dust."

The fourth and last volume of the "Inquiries" was issued in 1796; and in this the author took occasion to announce that he was engaged in preparing a work on Diseases of the Mind. This volume opens with an account of another epidemic of yellow fever, by which Philadelphia was visited in 1794. Dr. Rush contends earnestly for the doctrine, so unpalatable to the citizens, that the fever was of local origin, and depended upon accumulations of filth which it was in their power to

remove, even going so far as to say that he believed the time would come when municipal authorities would be held responsible for the spread of all such fevers. "Seasons and climates," he continues, "are not necessarily sickly. The sun would seldom strike by day, nor the moon by night, were pains taken to prevent the accumulation and putrefaction of those matters which occasion malignant fevers." He believed, when first asserting this opinion, that it was new, but, discovering his error, he was careful to state that it had been advanced by Dr. Thomas Bond, as early as 1766, in a clinical lecture at the Pennsylvania Hospital. At one time Dr. Rush regarded the fever as contagious, but he candidly admits that he was convinced by the arguments of his pupil, Dr. Charles Caldwell, that "the pestilence is devoid of any such power."

One of the papers in this volume is an inquiry into "the proximate cause of fever," which he found in spasm of the extreme bloodvessels; but the leading paper is a defence of bloodletting, which brings out all his power and eloquence as an advocate. It is written with the earnestness and spirit of one who felt himself engaged in establishing a great truth; who believed that he was contending for a principle that involved the interests of his race. While candid in its statements, his defence is heroic in spirit, and its influence in popularizing the use of the lancet was felt in every part of our country. The practice is now spoken of as "atrocious." There can be no doubt that bloodletting was carried to excess by Rush and his followers, but it admits of a doubt whether the practitioners of the present day have not run to the other extreme.

In this volume, and in connection with bloodletting, Dr. Rush repeats a belief which he had before expressed, that the pains of labor would be annulled by the discovery of an anæsthetic. This was no mere guess, but an opinion reached by a process of induction. "I was encouraged to cherish this hope," he says, "by having known delivery to take place in one instance during a paroxysm of epilepsy; and having heard of another during a fit of drunkenness in a woman attended by Dr. Church, in both of which there was neither consciousness nor recollection of pain."[1]

In 1798, Dr. Rush published a volume of "Essays; Literary, Moral, and Philosophical," which had previously appeared in the magazines of the day. It is in one of these that he contends against the ancient languages as a necessary part of the education of students of medicine. In 1801 he added to his other works a volume of Introductory Lectures, in one of which he unfolds his views on the unity of disease. Nosology appeared to him mischievous, as directing the attention of practitioners to the name rather than the character of the disease; and in his lectures he inveighed warmly against it. Rising from his chair, to give greater emphasis to his words, he would exclaim, *Nosologia delenda est!* But this question, in which he was able to create a lively interest while he was the popular teacher of the period, has long since been put to rest. His great work on Diseases of the Mind appeared in 1812, only a short time before the death of the author, which took place in 1813.

This work, the result of a lifetime of careful observation and honest inquiry, is, of all his writings, the one now most read and most frequently quoted by medical authors. Nearly all who have followed him on psychological medicine, refer to it as one of the most instructive of the treatises on that subject, and as especially rich in facts. Adopting the enlightened views which Pinel had just promulgated in France, Dr.

[1] Inquiries, vol. iv. p. 376, 3d ed.

Rush gave an impetus to the revolution which this country has witnessed in the management of the insane; and it is his noble eulogy that he aided "in opening the prison doors of the maniac, unbarred his noisome dungeon, and knocked the shackles from his limbs, substituting moral treatment for brute force, and love for fear."[1] He saw, as the great French alienist had pointed out, that the law of kindness is the true one in the management of lunatics; his work gave currency to the novel idea, and, as a result of the light diffused abroad by him, the condition of the insane in all our asylums has been one of steady improvement from his day to our own.

In the century that has passed away since Rush appeared as an author, no one of all the medical writers of America has attained to the popularity which he enjoyed, nor exerted so wide and lasting an influence on the professional mind of his country. During the generation in which he lived he was more generally read and followed, not only than any other medical author of this country, but than all our other writers on medicine put together. Nor is it likely that his name or his works will be forgotten. His writings form, as a whole, a body of philosophical medicine—defective, indeed, in many points—but exhibiting a breadth of view, an originality of thought and conception, an accuracy and extent of observation, and a terseness, vivacity, and clearness of style, that compare well with the best medical works of their period.[2]

A host of minor writers on yellow fever was brought out by the epidemics, as they appeared toward the close of the last century in our Atlantic cities. Among these was Dr. William Currie, of Philadelphia, whose writings on that subject were only less voluminous than those of Rush. He was an independent thinker, a careful investigator of the diseases of the country, and a faithful observer and recorder of facts; but he is likely to be longest remembered for the violence with which he assailed Rush's doctrines and practice. It is, however, due to his memory to record that he retracted publicly, soon after making the harsh strictures on his great contemporary.[3]

[1] Dr. Edward Jarvis.

[2] Before the first volume of Rush's Inquiries was written, Samuel Stanhope Smith, D.D., President of Princeton College, had published a small volume on "The Causes of the Variety of Complexion and Figure in the Human Species," which was republished, with notes, in Edinburgh, by a professor of that university. Dr. Caldwell reviewed it with great acrimony, urging the insufficiency of the causes assigned to produce the existing varieties. The question has been much discussed since that day, but remains still in an unsatisfactory position. In 1781, Dr. James Tilton published a short treatise on the Diseases and Management of Military Hospitals. Dr. Samuel Tenney published, in 1783, an Account of the Saratoga Springs. In 1786, Dr. Matthew Wilson produced an essay on the diseases arising from the air, contending that most of them are generated by miasmata. The same year he wrote for Atkins's American Magazine an account of a malignant fever which prevailed in Sussex County, Delaware, in 1774; and also an account of the severe winter of 1779, which appeared in the Transactions of the American Philosophical Society. In 1788, the Medical Society of the County of New Haven, Conn., published a volume of Transactions, which was much quoted by British writers. In 1793, part of a volume of Transactions was published by the Philadelphia College of Physicians, which, after many years, began to issue a quarterly summary, and now publishes annual volumes. Dr. Charles McLean wrote a work, in 1797, to prove that pestilential diseases were dependent, in all cases, upon certain altered conditions of the atmosphere, and were never communicated by contagion. An oration delivered at the University of Virginia, by M. Coste, Medical Director of the French forces, in 1782, forming a volume of 103 pages, 8vo., was printed at Leyden in 1783. Dr. John Leigh, of Virginia, obtained in 1785 the Harveian prize for an essay on the properties of opium, which was printed at Edinburgh in 1786.

[3] Dr. Currie published, in 1792, a historical account of the climate of the United States. In 1798 he wrote on the causes and cure of remitting or bilious fevers. In 1800 he wrote

Few of our authors on yellow fever are entitled to more honorable mention than Dr. Richard Bayley, of New York, who before writing on this subject had acquired a reputation abroad by his researches in membranous croup. His history of yellow fever in New York is one of the most graphic and instructive produced in our country, and affords evidence of powers which might have placed him in the front rank of our writers, had he lived to develop them; but his fearlessness in visiting the localities in which the epidemic raged, brought on an attack of the fever, which terminated his life just as his labors promised the greatest usefulness to his profession. Another writer, who afterwards rose to great distinction, was Dr. Charles Caldwell. He began to write on yellow fever while yet a student of medicine, having seen much of the epidemic in Philadelphia, in 1793. Of those who contended against its contagiousness, and for its domestic origin, he was among the first and the most earnest. He also wrote against the expediency of quarantine. Dr. John Beale Davidge, at that time a young physician in Baltimore, was also an early writer on yellow fever. He published a paper on that subject in 1798, in which he contended for the doctrine that the fever originated in the places where it prevailed, believing, when he asserted it, that it had not before been taught in this country.[1]

Our medical journalism commenced in New York towards the close of the last century. The first journal was a reprint, in 1790, of the Journal de Médecine Militaire, annotated from the French by Joseph Brown. The Medical Repository made its appearance on the 26th of July, 1797, under the editorial care of Dr. Elihu H. Smith, Dr. Edward Miller, and Dr. Samuel L. Mitchill. Its origin marks an important era in our medical history. Its editors were men of marked ability. Dr. Mitchill was especially noted as a theorist, but he was admirable for the extent and diversity of his attainments, and in versatility of powers had no superior among the medical men of his day. Dr. Miller was an original thinker, an acute observer, of solid judgment and learning, and a pleasing writer. Dr. Smith, the projector of the work, and the most gifted of the remarkable triumvirate, fell a victim to yellow fever in the twenty-seventh year of his age, but not until after he had achieved a national reputation. Among the productions

a sketch of the rise and progress of the yellow fever of 1798 in Philadelphia. In 1811 he wrote a treatise on the diseases most prevalent in the United States at different seasons of the year; and in 1815 he published a synopsis of the theories and doctrines of disease. Other writers were the following: Deveze, who has the distinction of having been the first American writer to declare against the contagiousness of yellow fever; Cathrall, who wrote, in 1796, on the synocha maligna of Philadelphia; Dr. J. O'Reilly, who, in 1798, wrote on the "Contagious Epidemic Yellow Fever" of that city; Seaman, who wrote, in 1796, on the yellow fever of New York; and Dr. Samuel Brown, who, in 1797 and 1800, wrote on the yellow fever of Boston. Noah Webster also published, in 1796, two volumes on Pestilential Diseases, forming a valuable work of reference. Among other writers at that period were Hardie, Tytler, Pfaff, Hosack, and Davis. J. Henry C. Helmuth, of Philadelphia, wrote a tract in German "for the reflecting Christian," in which he presented the subject in its religious bearings. Ffirth, a few years later, published a number of experiments made to determine the question whether the disease could be communicated from person to person. One of these experiments was to swallow the black vomit.

[1] To the list of our early writers on yellow fever, the following names are to be added: Matthew Carey, Pascalis, Condie and Folwell, Chadwell, Manly, Rushton, Addoms, Martin, Monson, and Monson, Jr. The various publications relating to the early epidemics of yellow fever on our continent would form a curious body of medical literature, which it would be interesting to study. While the discussions were going on about the nature and treatment of yellow fever, Drs. Yates and McLean found time to write a volume of a hundred and fifty pages on the Brunonian theory of Life.

left behind him to testify to his genius, is a poetical introduction to Darwin's "Botanic Garden." The Repository, under these gentlemen's guidance, acquired great popularity and influence, reaching every part of the country, and receiving contributions from its best writers. Among other articles were Physick's report of his autopsies in yellow fever, and the papers of Stearns and Prescott announcing the oxytocic properties of ergot. In the hands of numerous editors the Repository continued until it reached its twenty-third volume.[1]

In 1805, Dr. Caldwell, who had become widely and favorably known by a translation of Blumenbach's physiology, and by his writings on yellow fever and quarantine, issued a volume of Select Theses, written by graduates of the University of Pennsylvania, with a preliminary discourse and appendix from his own pen. A second volume followed in the succeeding year, the appendix containing a paper by the editor on the "vitality of the blood," one of his favorite doctrines. It was his purpose to continue the work annually, but the trustees, by the advice of the Medical Faculty of the University, saw fit to relieve candidates of the burden of printing their theses, and in consequence Caldwell's publication fell through. Strangely enough, he looked upon the action of the faculty in this matter as "a measure of vengeance and mischief" to himself.

Dr. Caldwell was one of the most prolific of American medical authors. His writings were fragmentary, consisting of essays, reviews, and discourses, scattered through the literary magazines and medical journals of the day, but if collected would make not less than ten octavo volumes of a thousand pages each. Almost always in a controversy on some point in medicine or medico-theology, he was seldom lost to the public eye from the time he entered his profession till near the close of his life. He was a man of varied attainments, but his learning was remarkable for extension of surface, rather than accuracy or depth; and, while he wrote on a great variety of subjects, it cannot be said that he added much to the stock of medical science. It was a peculiarity of his mental constitution that he continually set himself to advocate opinions and systems generally rejected, and to assail the most cherished beliefs of men. "Better occasionally broach startling error, than deal continually in time-beaten truisms," was one of his maxims; and it may be said that he wasted his fine powers, as another great scholar declared he had wasted a life, "in levities and strenuous inanities." Many of his best years were devoted to the exposition and defence of phrenology, which, towards the close of his career, was superseded by mesmerism and spiritualism. Such was

[1] The New York Medical Repository was followed, in 1803, by a periodical at Philadelphia, the Philadelphia Medical and Physical Journal, edited by Dr. Benjamin Smith Barton; but this contained too much botany and zoology to suit the profession, and it expired at the end of the third volume. It was succeeded, in 1806, by the Medical Museum, under the editorial care of Dr. John R. Coxe, which was continued seven years. In 1808 a journal was started at Baltimore, by Dr. Tobias Watkins, the Baltimore Medical and Physical Recorder, which had a brief career, and gave place to another in that city, of still shorter duration, edited by Dr. Nathaniel Potter, under the name of the Medical and Philosophical Lyceum. In 1810 the American Philosophical Register was set on foot by Dr. Hosack and Dr. J. W. Francis, at New York, its fourth volume containing the famous letters of Dr. Mitchell to Dr. Franklin on yellow fever, communicated by Dr. Rush to Dr. Hosack. The Eclectic Repository and Analytical Review was started at Philadelphia in 1811, by Drs. Otto, Hewson, James, and other physicians of that city, and reached its tenth volume, when it was discontinued. Among its notable papers is a brief account of McDowell's renowned operations for diseased ovaria. In 1812 the New England Journal of Medicine and Surgery was established by a number of the physicians of Boston.

his assurance of the truth of organology, that he advised the use of the trephine to the head in mania, over the part of the brain indicated by phrenology as affected. He wrote an analysis of fever which would have possessed value if it had been the fruit of clinical observation; but it was purely a work of the closet. As a writer of critical reviews, he was one of the readiest, most affluent, and most formidable of his day; in tone somewhat too domineering and dogmatic, and in language often unnecessarily bitter, but always vigorous and independent. His most elaborate work was an autobiography published since his death, which has added nothing to his fame. Exhibiting, throughout, the temper which caused him to suspect his old friends and teachers in the University of Pennsylvania of framing "a measure of vengeance" against him, he is everywhere unjust to the memory of his contemporaries.

About the beginning of the present century, the first works on systematic medicine began to appear, nearly all up to this time having been monographs. In 1801, Dr. B. S. Barton published some contributions for an essay towards a Materia Medica of the United States, having commenced in 1798 to make collections for such a work. In 1803, he issued a work on the Elements of Botany, with some references of a desultory character to vegetable physiology. Dr. J. R. Coxe, in 1806, compiled a Dispensatory, which in the scarcity of medical books at the time proved of much service to practitioners.

In 1807, Dr. Samuel Bard, of New York, gave to the profession a small but admirably written volume on the Science and Art of Midwifery. His "compendium" was the *vade-mecum* of our accoucheurs for more than a quarter of a century, and is still quoted with respect by writers on obstetrics. Its sound judgment and good sense made it a safe guide, and the clearness and simplicity of its language adapted it to the capacity of midwives, in whose hands, when it appeared, was most of the obstetrical practice of the country.[1] In 1810, Dr. James Thacher prepared a valuable Dispensatory, on a plan which had been proposed by the Medical Society of Massachusetts for securing uniformity in the Pharmacopœias of the United States; this work remained long in use by the profession.

In 1811 appeared the System of Anatomy, by Dr. Caspar Wistar, of the University of Pennsylvania, which was the popular text-book in American medical schools for more than thirty years. It passed through nine editions, enriched and enlarged by successive editors, its author having died shortly after the publication of the second volume. Wistar was the first writer on anatomy to describe accurately the extremities of the ethmoid bone, which previously had been supposed to belong to the sphenoid, and hence they have ever since been known as "the pyramids

[1] Dr. George C. Shattuck, in 1808, published three dissertations on Boylston prize-questions for 1806 and 1807. They treated of Diseases of the Skin, Mortification, and Biliary Concretions. Dr. Edward Cutbush, of the U. S. Navy, wrote in 1808, a work on Preserving the Health of Sailors and Soldiers. In 1808 and 1811, the monograph of Dr. Bayley on Membranous Croup appeared in the Medical Repository. The true nature of the complaint had been pointed out by him as early as 1781 in a letter to Dr. Hunter. In 1809 Dr. J. C. Warren published a valuable paper on Organic Diseases of the Heart. Dr. Nathan Strong, in 1810, wrote a treatise on Spotted Fever, which was followed the next year by papers on the same subject by Dr. North, Dr. Woodward, Dr. Bester, and Dr. Fish. Dr. Hugh Williamson, in 1811, published Observations on the Climate of different parts of America, to which he added a history of North Carolina, including an account of its diseases in 1812.

of Wistar."[1] His volumes contained little that was original, but the matter was presented in a shape highly convenient to students, and it is not too much to say that their publication marked an era in the history of American authorship.

Of scarcely inferior popularity at the time, and of the greatest value to the profession of our country, was another work which proceeded from the same institution a few years later. The "Elements of Surgery," by Dr. John Syng Dorsey, in two volumes, appeared in 1813. The author was a young man, and could not claim to have had much personal experience in surgery, but that of his distinguished uncle, Physick, then, as long afterward, the leading surgeon of the United States, was at his command with which to enrich his work. It was written in a simple, graceful, flowing style, with special reference to the needs of students, and so well did the author succeed in his design that his book was at one time adopted in the University of Edinburgh as a text-book. That place it assumed at once in our schools, and maintained until later systems supplanted it. Nor was it less prized by the profession as a work of reference. It passed through four editions, two after the author's death, which occurred while he was still young. Had he lived to discipline and mature the high gifts with which he was endowed by Nature, he would have attained undoubtedly to great eminence as an author. He indulged occasionally in poetical effusions, some of which, says Professor Gross, his biographer, "embody uncommon vigor of thought and power of description." Something of the glow of poetry may be detected in his professional writings.

At all times, while acknowledging his indebtedness to foreign surgeons, Dorsey does not hesitate to criticize their prejudices and practice. Thus, in the preface to his Elements he says: "Great Britain and France have been foremost in the cultivation of modern surgery, but their deficiency in philosophical courtesy and candor has in some instances greatly retarded its progress. To illustrate this remark it will be sufficient to state that the doctrine of adhesion, so ably developed in England, has been shamefully neglected in France; and that French surgery in fractures finds no advocates in Britain. Some of the best writings of Desault have never been translated into the English language, and those of Hunter are unknown or disregarded throughout the continent of Europe. This spirit of hostile rivalship, extending from the field of battle to that of science, cannot fail to exert a pernicious influence on practical surgery; a truth too palpable to escape the observation of any foreigner who visits a European hospital. An American, in walking their wards, sees with surprise in London a fractured thigh rudely bound in bundles of straw, and the patient discharged limping with a crooked limb. In the French capital he witnesses an amputation, and is disgusted with the officious zeal with which the surgeon crams a handful of lint between the stump and the flap which covers it, with an express design to prevent their adhesion."

While the University of Pennsylvania was contributing thus liberally to our literature, the University of Maryland was not idle. Dr. Davidge, its honored founder, in 1812, essayed another System of Nosology, more simple and therefore more eligible than that of Cullen then prevailing. In 1814 he republished his memoir on yellow fever, and with it his inaugural thesis on the Catamenia, in a volume entitled "Physical Sketches,

[1] Gross, Introductory Lecture on American Medicine.

or outlines of correctives applied to certain errours in Physick," which, besides these, contains an elaborate history of the various methods of amputation, including one of his own. The introduction to his Nosology contains a powerful argument against Rush's theory of "the unity of disease," which at that time excited a good deal of interest. His thesis, written in Latin, and first printed at Glasgow in 1793, maintains the doctrine that the menstrual flux is a true secretion. Not the least pungent article in his sketches is the review of a case related by Caldwell in his paper on the vitality of the blood. The case was as follows: The writer, after the extraction of a tooth, had some trouble with hemorrhage, but, keeping the blood in the alveolus by pressure, at last arrested its flow. The weather being warm, he examined the coagulum several times a day, but instead of its becoming "putrid and offensive, he was surprised to observe it on the fourth or fifth day after coagulation beginning to assume the appearance of flesh." And this incarnation commenced, he relates, not at the circumference, "but in the centre of the coagulum, at the greatest possible distance from any vessels that might, by elongation, have been protruded from the adjacent gums;" so that "what had been at first nothing but congealed blood, became a piece of perfect flesh, similar in texture and appearance to that of the gums." Upon this remarkable case Davidge makes the following comments: First, that it is "solitary of its kind;" then, that the clot is singular "from its transparency," all other clots of blood being opaque; and, finally, he is bold to say, that "the asserted fact is bottomed upon the broad basis of human credulity."

As a controversialist, Davidge displayed undue acerbity, as the reader will conclude from the foregoing quotation. His style, at the same time, was stiff, involved and affected, entirely unlike that in which he lectured. His lectures, indeed, afforded a model of simple elegance, while the moment he took pen in hand he seemed to forget the English idiom. Ten years after the appearance of his "sketches," he issued the first number of a journal, The Baltimore Philosophical Journal and Review, which he proposed to continue, but was obliged to give up for want of encouragement. The number published was written almost entirely by himself, in his peculiar, crabbed style, and in a temper so acrimonious that it was hardly read at all when it came out, and might soon after have been bought almost as waste paper.[1]

In 1816, a syllabus of the lectures of Dr. James Jackson in the Massachusetts Medical College, was published, and only increased the general feeling of regret that the learned and able author did not prepare a systematic treatise on the principles and practice of medicine.

In 1817 was published a volume of lectures on the "Elements of Therapeutics and Materia Medica," delivered by Dr. Nathaniel Chap-

[1] Dr. J. W. Francis in 1811 published an able paper on Mercury. It was in 1813 that Dr. Prescott wrote his article on Ergot, which was inserted in the thirteenth volume of the Dictionnaire des Sciences Médicales. The same year Dr. John Warren wrote ably on Calomel, arguing against its utility in hydrocephalus. Dr. Charles Wells, a native of South Carolina, also published that year, in London, his philosophical theory of dew, which was crowned by the Royal Society in 1814 with the Rumford medal. Dr. E. Hale, Jr., in 1814, published an instructive volume on spotted fever; and in that year Dr. J. Dyckman produced an elaborate dissertation on the pathology of the human fluids. Dr. Joseph Gallup, in 1815, contributed a practical work on the epidemic diseases of Vermont from its first settlement. In the same year Dr. Job Wilson wrote an inquiry into the nature of spotted fever, and Dr. Ennalls Martin produced a history of the epidemics of the winter of 1813 and 1814 in Talbot and Queen Anne's counties, Maryland.

man in the University of Pennsylvania, to which a second volume succeeded in 1819. Nothing so fresh in style, or so original in theory, had been contributed to our literature since the days of Rush. These lectures were received by the profession with abundant favor. As "discourses" they were characterized by some redundancy of expression, and a severe critic would have termed their style florid; but they were, perhaps, more pleasing to youthful readers on that account. The writer remembers well the feeling of relief, not to say delight, with which he turned to them from the dry treatises on Materia Medica, and the drier dispensatories which they came to supplant. Chapman's theory of the operation of medicines was of modern date, as he expressed it, and of captivating simplicity. It was this: "That all such agents act by exciting a local impression, which is extended through the medium of sympathy." No article, he held, "ever enters the circulation as a medicine." "It cannot, indeed, be credited," he says, "that any substance, after a subjection to the digestive and assimilative process, retains in the slightest degree its original properties." Besides this, everything that acts upon the system "is a stimulant." Such was his philosophy in a few words, which one of his critics hardly ventured to controvert when it was announced, feeling himself *tibi miles impar.*[1] How successfully it has since been opposed need not be related here.

With this popular work came out some numbers in quarto of a treatise on the "Vegetable Materia Medica of the United States," by Dr. W. P. C. Barton, of the same University; and a treatise on Medical Botany, of much research and substantial value, in three volumes octavo, by Dr. Jacob Bigelow, of Harvard University. The work of Barton was subsequently issued in a form magnificently illustrated, under the name of "Flora of North America."

In 1817 was originated a Journal of Science, which, though not medical in character, exerted a decided influence on medicine in the United States. This was the "Journal of Science and Art," projected at New Haven by Prof. Benjamin Silliman, of Yale College. The work remained under his editorial care until it reached its fiftieth volume. No American serial, it may be safely said, has contributed more to the fame of our country, and none has done so much to develop its science in the direction of natural history. Its volumes form a magazine of facts and observations indispensable to writers on any branch of natural science, and contain many articles relating directly to medicine. Among the authors of our country it would be difficult to name a writer more polished and graceful, or more variously gifted and informed, than the elder Silliman, who devoted a long life assiduously to the advancement of useful knowledge among his countrymen, and who, on retiring from his work as editor, had the good fortune to find in his own family successors qualified to sustain the high reputation of his journal. Under the direction of Prof. B. Silliman, Jr., and Prof. James D. Dana, the American Journal of Science has maintained its rank as one of the leading periodicals of the world.

Dr. James Thacher, in 1817, published a work styled the "Modern Practice of Physic," the reception of which by the profession was so favorable that a second edition was called for in a few years. Dr. Thacher was at the same time a scholar and a practical physician, equally at home in the sick-room, in writing on the nature and treat-

[1] See Med. Recorder, vol. i. p. 189.

ment of disease, or in drawing up his well-known biographical sketches of noted American physicians. His is one of the names which will be long held by the profession in grateful remembrance.[1]

In 1818, Dr. Nathaniel Potter, the learned Professor of Theory and Practice of Medicine in the University of Maryland, published an elaborate memoir on Contagion, more especially as respects the yellow fever. In the same year the Medical Recorder, which for a time was the most influential journal of medicine in the country, was set on foot by several respectable physicians of Philadelphia. Drs. Eberle, McClellan, and Calhoun were subsequently announced as its editors. In 1829 it was merged in the American Journal of the Medical Sciences. Among other interesting papers it contains a report of the famous operation of Deaderick, of Tennessee, for removal of the lower jaw, the first on record. Many other papers by the ablest medical writers of our country found their way into the Recorder.

In 1819, the first American works on Chemistry appeared. Dr. John Gorham published his Elements of Chemical Science in two volumes; and Dr. Franklin Bache, of Philadelphia, prepared an elementary treatise on chemistry about the same time. During this year, also, was announced a new theory of Galvanism, with an account of the calorimotor, a new galvanic instrument, by Dr. Robert Hare, the gifted Professor of Chemistry in the University of Pennsylvania.[2]

The United States Pharmacopœia, proposed in 1808 by the Massachusetts Medical Society, was issued in 1820, and having been repeatedly revised at intervals of ten years, retains its place among our standard works as a book of reference. In 1820 also was established the medical journal which has done more than any other of our serials to advance and shape the medical literature of the United States. Dr. Nathaniel Chapman, Professor of Theory and Practice in the University of Pennsylvania, started that year the Philadelphia Journal of the Medical and Physical Sciences. In the inception of the enterprise he was alone, but in a short time he secured the valuable assistance of Drs. Dewees and Godman as associate editors. From the beginning, the Journal evinced the vigor to have been expected from the editorial talent engaged upon it. Its editor in chief was then in the prime of his great intellectual powers, and Godman had already given proof of a genius rarely equalled in our profession.[3] In 1827, the name of the Philadelphia Journal was changed,

[1] Dr. James Mann, of New York, contributed an interesting History of the Campaigns of 1812, 1813, and 1814, to which are added surgical cases, and observations on military hospitals and flying hospitals attached to a moving army. Dr. Jabez Heustis published, in 1817, Some Physical Observations and Medical Facts and Researches on the Topography and Diseases of Louisiana. In the same year, Dr. W. C. P. Barton issued a work on the Internal Organization and Government of Marine Hospitals, based on his own experience and observation. The year following, Dr. John King published, at Norwich, a treatise on Extra-uterine Fœtation and Retroversion of the Uterus. Dr. J. C. Shecut, of Charleston, the same year, produced an Essay on Contagions and Infections. Dr. A. H. Stevens published some cases of Fungus Hæmatodes of the Eye, in 1818.

[2] This year appeared also a work by Dr. L. Spalding, of New York, entitled Reflections on Yellow Fever Periods; one by Dr. Felix Pascalis, on the Malignant Yellow Fever of New York in 1819; and one by Dr. Shecut, of Charleston, containing a history of Yellow Fever.

[3] The first account of that strange disease, "Milk sickness," so far as is known, was given by Messrs. Lea and McCall, students of medicine from Tennessee, in one of the earlier numbers of this journal, and it is proper to record that the editor was disposed to reject their history of this disease as apocryphal, for the reason that the facts stated seemed wholly irreconcilable with his hypothesis that poisons in a formal state never entered the circulation.

and it passed into the hands of Dr. Isaac Hays, who, with a judgment, perseverance, and industry, seldom witnessed in journalism, has continued it down to the present day, as the American Journal of the Medical Sciences.

This is the medical journal of our country to which the American physician abroad will point with greatest satisfaction, as reflecting the state of professional culture in his country. For a great many years it has been the medium through which our ablest writers have made known their discoveries and observations.

In 1821, Dr. Hosack's Nosology, which had been issued some years before, reached a second edition, and the Journal of Foreign Medical Literature was set on foot, by Drs. Emlen and Price, and afterwards continued for a time by Drs. Godman and Littell. Dr. Donaldson, in 1821, published a treatise on the present system of medicine and surgery in Europe and America; and Dr. E. Hale, Jr., the same year issued an essay, which had been crowned by the Boylston prize, on the connection between the Stomach and the Urinary Organs.

The following year was an eventful one in the history of our medical literature. A work of much research was produced by Dr. John C. Warren, styled "A Comparative View of the Sensorial and Nervous Systems in Man and Animals;" a treatise, by Dr. John Eberle, on Materia Medica, was published; and two journals appeared, the New York Medical and Physical Journal, conducted by Drs. Dyckman, Francis, and John B. Beck; and the Western Quarterly Reporter, edited by Dr. John D. Godman, at Cincinnati, marking the rise of medical journalism in the Valley of the Mississippi. The Materia Medica of Eberle was a work of sterling merit, at once learned, practical, and judicious, and written in a clear, simple style. Those most partial to Chapman could hardly help admitting that, in all the qualities sought for by students and practitioners in a text-book or a manual, it was superior to his treatise on the subject. Its author, with far less genius, was a scholar of very much greater research, who had taken time to look extensively through the German and French literature on the subject as well as that in his own language, and to make his work as thorough as industry could render it. It was long one of the most popular text-books in our schools, as well as an authority in the profession. Dr. J. Bigelow, the same year, published a valuable treatise on Materia Medica, intended as a sequel to the Pharmacopœia of the United States. An era was opened in the professional literature of the West by the appearance of Godman's journal at Cincinnati, which, though of short duration, was the beginning of a most prolific series. Only six monthly numbers of his work were issued, but as proof of the activity and zeal with which the editor devoted himself to it, it is worthy of mention that, of the matter composing them, he wrote more than three hundred pages.[1]

The year 1823 is also memorable as having produced the classical work on Medical Jurisprudence by Dr. T. Romeyn Beck and Dr. John B.

[1] Dr. Godman, in 1824, published a thin octavo volume made up of anatomical researches, which was followed, the succeeding year, by a smaller volume, entitled Contributions to Physiological and Pathological Anatomy, founded on his own dissections. His American Natural History, in three volumes, appeared in 1826, and gave him standing with the naturalists of his time. A small volume, composed of Addresses delivered on various occasions, followed in 1829. The "Rambles of a Naturalist," written for a weekly magazine in Philadelphia, and published in a small volume after the author's death, was the last of his labors, all of which bore evidence of a passionate devotion to, and of a genius capable of the highest achievements in, science.

Beck. This admirable treatise has rather gained in reputation than declined during the many years that have elapsed since its publication; nor is there any reason why it should not maintain its enviable position among the works of its class, since the changes which, under a rapid succession of systems, are inevitable in other departments of medicine, are not met with in medical jurisprudence. Besides this learned work, which has conferred so much fame upon our authorship, others of note were written in 1823. One of these was on Diseases of the Eye, by Dr. George Frick, of Baltimore; and a larger one on Fevers, from the pen of Dr. Thomas Miner and Dr. Wm. Tully, two eminent physicians of New England, had the recommendation of being founded on the observation and experience of its authors at the bedside.[1]

Dr. William P. Dewees, who had become eminent in Philadelphia as an accoucheur, and was known in all parts of his country as a writer on obstetrics, appeared in 1824[2] as author of a System of Midwifery, which not only gave new dignity to the art in the New World, but may be said to have created an American School of Obstetrics. The popularity of this work was very great, and in thirteen years it had passed through a dozen editions. The author wrote from his own experience, and expressed himself as one having a right to speak. If he was dogmatic, it must be remembered that he was almost without a rival near him to question his authority, and if his pages betray haste and carelessness, the defect must be set down to the incessant press of business which left him little leisure for correcting what he wrote. There is something painful in the thought that a work once so much read, and held in such high esteem, should now be entirely neglected. But the march of science renders such a fate inevitable. Other systems more advanced have long since taken its place.

A treatise on the Diseases of Females, and one on the Physical and Medical Management of Children, followed Dr. Dewees's Midwifery in 1826, and extended his fame as an author. It was many years before either work was superseded, and while they stood their ground they were to be found in nearly every medical library of the country. In 1830 he entered a new field, sending forth a "Practice of Physic," comprising most of the diseases not treated of in his "Diseases of Females" and his work on Children; but this proved a failure. The writer had undertaken too much. Of all subjects pertaining to obstetrics, he was master, but his medical philosophy was tainted by the declining system of Broussais, and his therapeutics proved unpopular. As a specimen of his practice, it may be mentioned that he reports having bled one of his patients six times for a fever, brought back, after she was convalescent, by a single plate of soup.

Few more remarkable men have appeared in the American profession than Dr. Nathan Smith, author of a treatise on typhus fever written in

[1] The following works were also issued in 1823: An Essay on Suspended Animation, by Dr. Samuel Calhoun; a Guide for Practising Physicians in Visiting the Sick, by Dr. J. Lobstein; a Treatise on Cynanche trachealis, by Dr. W. Sweetzer, of Boston, who also wrote on Consumption and on Indigestion in 1836 and 1837; an Account of Yellow Fever in New York, in 1822, by Dr. T. S. Townsend; and a History of Yellow Fever as it appeared in Natchez, in 1822, by Dr. Henry Tooley.

[2] A work on the Philosophy of Epidemics was contributed in 1824 by Dr. Joseph M. Smith, and also three volumes of Essays on various medical subjects by Dr. David Hosack. The Medical Intelligencer, a monthly in quarto form, was started in the winter of 1823–4 by Dr. J. V. C. Smith, at Boston; and the Medical Review and Analytical Journal by Dr. Eberle and Dr. George McClellan, in Philadelphia, in 1824.

1824. He was a great surgeon, an able teacher, and a judicious author. In independence of thought, and in sturdy, common sense, he had few equals in his day, and has never had many superiors in the profession. When his little volume appeared, the distinction between typhus and typhoid fever had not been recognized, and it was evidently the latter that he had under consideration. "I have never been satisfied," he declares, "that I have cut short a single case of typhus fever that I know to be such. Typhus has a natural termination like other diseases which arise from specific causes." His readers, fresh from the work of Armstrong, on typhus fever, recommending a vigorous treatment by the lancet and purgatives, were not a little disappointed when they came to his concluding words as to its cure: "All that is required is simple demulcent drinks, a very small quantity of farinaceous food, and avoidance of all causes of irritation." Another work on surgery was produced in 1824, by a professor in the University of Pennsylvania, Dr. William Gibson. It was a heavy work, compared with that of Dorsey, and in comparison with later systems it was greatly wanting in information; but the author made amends for these early defects in succeeding editions, and his surgery acquired at last a just claim to the position given it by his official connections. It was not long in supplanting the treatise of Dorsey as a text-book in the American schools.[1]

In 1826, the North American Journal of Medicine and Surgery was established at Philadelphia, under the auspices of the "Kappa Lambda Society of Hippocrates." Its corps of editors embraced some of the best medical talent of the country. It included the names of H. L. Hodge, C. D. Meigs, B. H. Coates, F. Bache, and R. LaRoche, to which, after two years, those of John Bell, George B. Wood, and D. F. Condie, were added. The aim of the Society was to promote harmony in the ranks of the profession, and with its patronage the journal was expected to have wide circulation. It assumed at once a high rank among the periodicals of the day, but, notwithstanding its acknowledged ability, and the favorable circumstances attending its origin, it was discontinued at the end of the twelfth volume for want of adequate pecuniary support. A systematic treatise on anatomy was added to the list of American books in 1826, by Professor William E. Horner, of the University of Pennsylvania, one of the most pains-taking and assiduous of modern authors; but though fuller and more accurate than the volumes of Wistar, it failed to secure the footing in the schools so long maintained by our earliest work on anatomy.

Dr. James Rush produced, in 1827, a work on the Philosophy of the Human Voice, which for originality and depth of research has been pronounced by competent judges one of the most creditable of the productions of our country relating to medicine. The same year, the Monthly Journal of Medicine originated in Philadelphia, and Dr. Drake took charge of the Western Journal of the Medical and Physical Sciences, at Cincinnati. When he projected his periodical, he assumed as its motto, *E sylvis nuncius;* to which, no readers being secured east of the mountains, he added subsequently the words, *æque atque ad sylvas nuncius.*

[1] Dr. Thomas Miner gave an interesting account of typhus syncopalis in 1825, and an epitome of chemical philosophy was published the same year by Dr. James D. Dana. In 1825 also appeared a Manual of Chemistry by Dr. John W. Webster, Professor of Chemistry in Harvard University, who was executed at Boston in 1850 for the murder of Dr. George Parkman.

He conducted it with great energy for twelve years, when it was merged in a journal at Lonisville.[1]

In 1828, Dr. John E. Cooke produced a work in two volumes of decided originality. It was entitled a Treatise of Pathology and Therapeutics, and proposed a new theory of disease. The theory was one of the most compendious ever framed. It referred all fevers, with cholera, dysentery, and a host of other varying affections, to congestion of the *vena cava.* And his therapeutics were no less simple. All his remedial measures had reference to unlocking the liver by purgatives, at the head of which, in point of efficacy, he reckoned calomel. The aim being to secure bilious purging, cathartics were to be repeated, in increasing doses, until the effect was produced. In the end, this led to an abuse of calomel which brought it into great disrepute; and with its popularity the writings and the system of one of the most learned and conscientious of American authors have passed away. With this work, Dr. Cooke, in conjunction with his colleague, Dr. C. W. Short, started the Transylvania Journal of Medicine, which was edited by them for four years. At the close of the fourth volume it passed into the hands of Dr. L. P. Yandell. Dr. Robert Peter became its editor in 1837. Among its more valuable papers are the reports by Dr. B. W. Dudley of his operations for stone in the bladder, and his cure of chronic epilepsy by removing portions of the skull bone depressed by mechanical injuries.

The Boston Medical and Surgical Journal was also set on foot in 1828, by Dr. J. V. C. Smith, author of a work on the Fishes of Massachusetts. In that year, too, the Medical Biography of Dr. Thacher, a work not likely to be superseded, was contributed to our literature. A year later Dr. Horner produced his System of Pathological Anatomy, founded on original observations.[2]

In 1830, an elaborate work on Chemistry, by Prof. Silliman, was announced. Its arrangement was regarded as defective, and, added to this, its size unfitted it for the use of students, so that it never attained general currency; but as a repository of chemical knowledge interesting to all readers, nothing superior to it has been produced in the English language. Dr. Samuel D. Gross, who has since contributed so largely to the literature of the profession, appeared this year as author of a modest volume on the Anatomy, Physiology, and Diseases of the Bones and Joints, which, it is interesting to remark, contains the first account of adhesive plaster as a surgical appliance in fractures.[3]

In 1831, the classical work of Dr. John Bell on Baths and Mineral Waters appeared. The same author, in 1842, produced another work,

[1] Dr. Guy W. Wright and Dr. James M. Mason had started a semi-monthly, the year before, under the name of the Ohio Medical Repository. In 1832 the Western Medical Gazette was set on foot by the Faculty of the Medical College of Ohio, but at the end of nine months was suspended. It was revived five months afterwards by Dr. Silas Reed and Dr. Samuel D. Gross, who continued it until two volumes were completed. In 1842 the Western Lancet was projected at Cincinnati by Dr. Leonidas M. Lawson; and in 1847 the Dental Register of the West was started at the same place by Dr. James Taylor, of the Ohio College of Dental Surgery.

[2] In 1829 the Journal of Health was projected by Drs. John Bell and D. Francis Condie, at Philadelphia. A Formulary, which was greatly useful to the profession, was published by Dr. Benjamin Ellis; a System of Dental Surgery was contributed by Dr. Samuel Fitch; a Journal of Pharmacy was started by Dr. B. Ellis; and a treatise on the Distinct and Confluent Smallpox was produced by Dr. John D. Fisher.

[3] Dr. S. W. Avery, in 1830, issued a work, meant especially for the people, entitled "The Dyspeptic's Monitor."

written in the same elevated style, on Regimen and Longevity. The kindred topics of Alcohol in its Relations to Medicine, and the Importance and Economy of Sanitary Measures to Cities, were treated of in works issued in 1859 and 1869, and discussed with marked ability. Dr. John Eberle, in 1831, enriched our literature by two works of the highest merit—his treatise on the Diseases and Physical Education of Children, and his treatise on the Practice of Medicine. Nothing equal to them, in every respect, had been produced by an American writer. Not only were they admirable in style, but they were full, accurate, and practical in matter. Both were adopted as text-books in our schools, and passed through many editions before they were superseded.[1]

Dr. Nathan R. Smith issued a volume of great interest, in 1831, consisting of memoirs, medical and surgical, by his honored father, with additions from his own pen. In 1832 the same author contributed a work on the Anatomy of the Arteries, which was of value to the profession.

Dr. Amariah Brigham also, in 1832, commenced a series of publications which excited much interest among students of psychological medicine. The first treated of the influence of mental culture on health. It was republished in Glasgow, with notes by Dr. Robert McNish, and was followed, in 1836, by a treatise on the Influence of Religion on Health and the Physical Welfare of Mankind, which involved the author in an embittered controversy. With these a small volume was brought out by Dr. Brigham, in 1833, on Epidemic Cholera; and, in 1840, one of much more note and significance on the Diseases and Functions of the Brain, the Spinal Cord, and the Nervous System.

The leading production, however, of 1832, was the treatise of Dr. Samuel Jackson, on the Principles of Medicine. This volume came out with a heraldry before unknown in the literary history of our country. "Knowing the anxiety of the profession in regard to the forthcoming work of Dr. Jackson," said the leading journal of the Union, "we applied to its publishers for an early copy," which was duly noticed in terms of the strongest commendation. "Its publication," declared the reviewer, "will constitute an epoch in the history of American medical literature." For years before it was published it had been understood that the author was at work on a treatise in which justice should be done to the merits of physiological medicine; but, unfortunately for it, physiological medicine was about to vanish away when it appeared, and its interest declined with the system. One edition of it was sold, and the publishers proposed to issue a second; but the author would not consent to the labor of remodelling it in a way to make it conform to the medical science of the period, and no other was ever issued. It has been often repeated, without truth, that the work fell still-born from the press, and much has been credited to unfriendly criticism as the explanation of this defeat, but with only a show of reason. Certainly, if it was reviewed harshly in some quarters, in others it received, as has been shown, a full meed of praise. And the most formidable of its critics, a writer in the Transylvania Journal of Medicine, at Lexington, assailed it with

[1] The following works also appeared in 1831: Drawings of the Anatomy of the Groin, by Dr. William Darrach; a Treatise on Malaria, by Dr. U. Parsons; a small volume, by Dr. John Ware, on Delirium Tremens; a work on Chemistry, by Dr. Lewis C. Beck; a modest little volume of Essays on Materia Medica, by Mr. Geo. W. Carpenter; and a singular treatise on Dyspepsia, by Mr. O. Halsted, proposing to cure the complaint by shaking and kneading the digestive organs after eating.

arguments which rather recommended than injured it with most readers. The chief objections urged against it by this reviewer were that it leaned to humoralism in pathology, and ignored the claims of phrenology. The book failed, so far as it was a failure, because its philosophy was defective. It perished with the narrow and fanciful system which the author himself lived to renounce as unfounded.

The treatise of Dr. Robley Dunglison on Physiology also appeared in 1832, and formed a contribution to our literature which all readers hailed as of true value. It was such a compend of physiological science as was before nowhere extant in the English language; incomparably superior to the works of Bostock, Richerand, and Blumenbach, which had previously been the dependence of our students of medicine. Availing himself freely of the labors of others, the author's aim was to present a view of the existing state of physiology, without any straining after originality; so that his volumes are marked by learning rather than novelty of doctrine, but are none the less valuable to students on that account. The style in which they are written is unambitious, simple, clear, and pleasing. That many of his views were not accepted at the time, and that not a few have since been set aside, is what was to have been expected in a science advancing like physiology; but his work, the most advanced of its day, forms a rich treasury of facts and learning which the student may still consult with advantage.[1]

A work in some respects the most fortunate that has been produced in America, appeared the next year in Philadelphia. In 1833, the United States Dispensatory, the joint production of Dr. George B. Wood and Dr. Franklin Bache, two of the ablest medical scholars of our country, was published, and at once took the foremost place among American works of its class. Nearly half a century has been completed since it was brought before the profession, but it may be doubted whether its standing was ever higher than it is at the present day. Its authors commenced life in Philadelphia about the same time, and were early friends. When they rose to distinction they were called to teach in rival institutions, but the jealousies of the schools, if any ever arose, never entered their studies, nor for an hour disturbed their fraternal relations. Laboring on together as edition after edition of their great work was called for, one on the chemical, the other on its botanical department, their cordial intercourse ceased only when one of the laborers was called away by death. Dr. Wood, who survives to enjoy the fruits of his honorable industry, may well recount this enduring friendship as among the greatest blessings of a fortunate life.

In 1833 the profession was enriched by a work which may be said to have enlarged our knowledge on some points in physiology more than all that had preceded it—a work that resulted from an accident. Dr. William Beaumont, a surgeon in the United States Army, had the rare opportunity of observing how digestion is accomplished in the human stomach. A Canadian soldier received a wound from the discharge of a gun, that exposed the interior of his stomach to view. An orifice remained after his recovery, through which food could be introduced, and

[1] In 1832, Dr. Thomas D. Mitchell brought out a treatise on Chemistry, on the basis of that of Reid, his chief additions to which consisted in an argument to show that alcohol might be dispensed with not only in medicine, but in pharmacy. Dr. I. Hays originated, in this year, the Cyclopædia of Practical Medicine, to which some of the best writers in our country contributed articles. Dr. James Jackson, Jr., published also, in 1832, a small volume on Cholera, made up of cases which he had witnessed in the Paris hospitals.

the action of the gastric juice upon it noted. The results of his numerous experiments and observations, in many of which he had the aid of Dr. Dunglison, are given by Beaumont in a volume which must remain in all coming time an authority on the subject of digestion. Some of the facts first established in the case of his patient will find a place in every treatise on physiology.

With this valuable monograph, another work appeared in 1833, most creditable to the literature of medicine in our country. This was the medical dictionary of Dr. Dunglison, which has gone on increasing in popularity with the profession from year to year. It was at first issued in two volumes, and contained biographical notices of many of the most eminent medical men of the world, but this feature disappeared in the second edition, the author finding that the biography would swell his work to an inconvenient size. Each successive edition has increased the value as much as the bulk of the dictionary, which it is safe to say stands now unrivalled in the English language. Dr. Dunglison's son, fortunately for the profession, has inherited the gifts which rendered his father the first of medical lexicographers, and promises to maintain the work in its present high position during at least another generation.

Dr. E. Geddings, of the University of Maryland, set on foot another periodical, the same year, the Baltimore Medical and Surgical Journal and Review, but though among its correspondents it numbered such writers as T. R. Beck, N. Potter, and N. R. Smith, it fell through after a few months. Dr. Samuel Metcalf, this year also, added something to our literature in the shape of a small volume presenting a new theory of terrestrial magnetism. Magnetism, he held, was but another form of caloric, which, passing from south to north, gave the directive force to the needle. Ten years later, and after much investigation of the subject abroad, he published, in London, a second and much larger edition of his book. It cost the author, indeed, a vast amount of labor, which was but poorly requited either in fame or money, while the advancing years of his life were embittered by disputes with contemporary scientists about his claims to priority of discovery.

In 1834 numerous works were contributed. Dr. J. R. Coxe started an "Inquiry into the Claims of Harvey to the discovery of the Circulation of the Blood," in which he succeeded in showing that in this memorable instance, as in all cases before and since, the truth was not reached at once by the intuition of a single mind, but by the efforts of a succession of inquirers. Dr. Frost, of the University of South Carolina, published a volume of lectures on Materia Medica. Dr. Wm. W. Gerhard made a valuable publication on the cerebral affections of children, which he followed, in 1836, by a volume of lectures on the diseases of the chest, and, in 1837, by a clinical guide for students.[1] A work of much merit on Pulmonary Consumption was produced, in 1834, by Dr. Samuel George Morton, whose labors in other fields subsequently made his name illustrious in science. In 1849, he brought out a work on human anatomy, but, in 1839, he had published his great work, entitled "Crania Ameri-

[1] Dr. Gerhard's treatises were founded on clinical observations, from which they derived unusual interest. He did much for the education of his young countrymen in physical diagnosis of diseases of the chest; and was the first, or among the first, to point out the distinction between typhus and typhoid fever. He made the diagnosis unequivocal. He also called attention to the relation of hydrocephalus, in infants, to tubercular meningitis. Few more successful investigators than Dr. Gerhard have labored in our country to advance medicine.

cana." His "Crania Ægyptica" followed in 1844. His collection of crania enabled him to compare the cerebral capacity of most of the nations of the earth, thus furnishing data from which physiologists are able to draw interesting conclusions.[1]

Dr. James Jackson, in 1835, published a memoir of his lamented son, Dr. James Jackson, Jr., who gave promise of great distinction in his profession; and, in 1838, he reported a number of cases of typhoid fever, which occurred in the Massachusetts hospital; a paper which Dr. Bartlett found of the greatest service in the preparation of his work on fevers. In 1835, Dr. Dunglison published his scholarly work on Hygiene; Dr. John P. Harrison collected and published a volume of Lectures and Essays on Medical Subjects, which had previously appeared in another form; and Dr. John B. Beck issued a volume of Researches in Medicine and Medical Jurisprudence. A volume consisting of papers read before various learned bodies was also issued, by Dr. Richard Harlan, entitled Medical and Physical Researches, or Original Memoirs; it embraced valuable contributions to Zoology and Comparative Anatomy. But the most original work of this year, and, in its effects, far the most important, was the paper read before the Massachusetts Medical Society, by Dr. Jacob Bigelow, on Self-limited Diseases. The conception of such a class of affections did not originate with the author, but its existence was never so fully recognized before he wrote. The recognition has effected a revolution in the treatment of many complaints, while the class in which the principle obtains has been steadily extending since he called professional attention to it. Another work of this year, which, though a compilation, claims a favorable notice, is the First Lines of Physiology, by Professor Daniel Oliver, of Dartmouth College. It is an admirable digest of the facts of the Science. The Author was in advance of the Physiologists of his day in ignoring the pretensions of Phrenology, and in admitting the truth of certain phenomena in animal magnetism which rest, as Sir W. Hamilton expresses it, "upon a tenfold superfluous evidence."

From Dr. Dunglison's prolific pen another work appeared the following year; his General Therapeutics, or Principles of Medical Practice, with tables of the chief remedial agents and their preparations, and of the different Poisons and their Antidotes. But as it was a production of the closet, and not the result of clinical observation, though it was written by a profound and judicious scholar, it never took rank with his Physiology, or his Dictionary. Dr. John C. Warren this year published an elaborate treatise on tumors. During the year, an interesting prize essay, on the Physical Signs in Diseases of the Abdomen and Thorax, was published by Dr. R. W. Haxall, of Richmond.[2]

[1] Dr. Togno, in 1834, published a work on the Anatomy and Physiology of the Ear. Dr. Casanova published some observations on cholera morbus. Drs. Ogier and Logan issued a compend of operative surgery, and Dr. Edward Barton, who had appeared as an author in 1828, wrote a treatise on yellow fever.

[2] Dr. Caleb Ticknor, of New York, published, this year, a popular volume in Harper's Family Library, on the Philosophy of Living, taking for his motto the wise saying of Bacon, that "A man's own observation, what he finds good of, and what he finds hurt of, is the best physic to preserve health." And a volume was issued by Dr. Parrish, of Philadelphia, entitled Practical Observations on Strangulated Hernia, based on a large experience. Two new journals also appeared this year—the Electic Journal of Medicine, afterwards the Bulletin of Medical Science, projected by that indefatigable writer, Dr. John Bell, and the Southern Medical and Surgical Journal, at Augusta, Ga., edited by Dr. M. Anthony and Dr. Joseph A. Eve. Dr. Luther V. Bell, of New Hampshire, published this year some Observations on certain obscure and undecided Doctrines in relation to Smallpox, Varialoid, and Vaccination. Dr. George Bushe, of New York, in 1837, wrote a treatise on the

In 1838, also, a large number of works was issued, first among which, in ability and in the impression it produced, was the Philadelphia Practice of Midwifery, by Dr. Charles D. Meigs. Another was the Medical Jurisprudence of Insanity, by Dr. Isaac Ray, which treats ably of a subject too little understood by physicians. The lectures of Dr. Hosack on the Theory and Practice of Physic, edited by Dr. Henry W. Ducachet, were published this year, as were also Lectures on Lithotomy, by Dr. A. H. Stevens. Dr. Charles Hooker, too, produced a well written Essay on the Relations between the Respiratory and Circulatory Functions, while Dr. Tripler wrote on Recruiting, and Dr. J. W. Monette on Yellow Fever in New Orleans and Natchez; and the Philadelphia Medical Examiner, edited by Drs. Biddle and Clymer, was originated.

Dr. Henry I. Bowditch, the succeeding year, made an important communication in reference to thoracentesis in chronic pleurisy; an operation much opposed at first, but now generally conceded to be legitimate. It has been performed by Dr. Bowditch 325 times, and on 204 patients. To this valuable contribution to our literature, that author has added some interesting statistics relating to the influence of a wet soil on pulmonary consumption. Dr. Dunglison came out this year with still another book, entitled New Remedies, which, like all the productions of his pen, was marked by industry, sound judgment, and a clear English style. Dr. Samuel D. Gross, then a professor in the Cincinnati Medical College, produced a work of much labor on Pathological Anatomy, the first in our language to present a systematic view of the science, and useful in directing the attention of students more generally to that important study.

In 1840 the following works appeared: Dr. B. B. Shober, of Charleston, issued an Essay on Yellow Fever, designed to prove the transmissibility of the disease; and Dr. Upham wrote on Disorders of the Mind; but the great work of the year was from a professor in the University of New York, Dr. Martyn Paine, entitled Medical and Physiological Commentaries. Hardly a work issued from the medical press of America will compare with these ponderous volumes in the learning or in the tedious prolixity with which they are composed. Holding resolutely to an exploded medical philosophy, the author was born too late to command the reverence which his great erudition would have excited in an earlier age. His elaborate and exhaustive commentaries were followed, some years later, by a volume on Materia Medica, characterized by all their merits and all their defects. His volumes are works for teachers and writers, rather than for practitioners or students of medicine. Dr. Edward Warren published, this year, two Boylston Prize Essays, on Scrofula, Rheumatism, and Erysipelatous Inflammation. The Western Journal of Medicine and Surgery was started at Louisville. It succeeded to the Louisville Journal of Medicine, edited by Drs. Miller, Yandell, and Bell, two numbers of which were issued in 1838, and to the Western Journal of the Medical and Physical Sciences, thirteen volumes of which had been completed by Dr. Drake at Cincinnati. It was edited by Dr. Daniel Drake and Dr. L. P. Yandell, with whom, after the second year, Dr. T. W. Colescott was associated, and on the retirement

Malformations, Injuries, and Diseases of the Rectum. The American Intelligencer and Medical Library was set on foot the same year, by Dr. Dunglison. In it were republished many valuable English works on medicine. Dr. Doane also issued this year an illustrated Surgery, and Dr. Dunglison added his Medical Student or aids to the Study of Medicine.

of Drs. Drake and Colescott, some years later, Dr. T. S. Bell became one of its editors.

The only publications in 1841, of which I have been able to find any account, were a volume of Essays on Fevers, by Drs. Davidson and Hudson, and a Practical Dictionary of Materia Medica, by Dr. John Bell.

The following year, Dr. Elisha Bartlett, who had made himself known as one of the most elegant of our writers by his papers in the medical journals of the day, published his well-known work on Fevers. It was succeeded in 1844 by his Philosophy of Medical Science, and in 1848 he added his Inquiry into the degree of certainty in Medicine; three volumes which, for grace of manner and philosophical breadth of view, will not suffer by comparison with any medical works in our language. Dr. Samuel Forry also contributed to our literature, in 1842, a volume which attracted the attention and elicited the praise of the great Humboldt—his work on the Climate of the United States and its endemic influences. It will remain a lasting monument to the genius and industry of the lamented author. While preparing this treatise for the press, he also set on foot the New York Journal of Medicine and the Collateral Sciences, to which he continued to contribute largely, though with failing powers, until removed by death. The name of this young physician ought not to be passed over without at least a word of respectful commemoration. He was "learned, without any fondness for display; a lover of exact detail, but always searching for principles in the facts he accumulated so largely; a statistician, and yet a fluent writer. How entirely his devotion to his pursuits prevailed over the common weaknesses and interests by which most men are influenced, was shown by the fearless readiness with which he threw himself into the focus of a pestilential disease for the sake of studying its nature and causes, as a mere episode in a pleasure trip which he had undertaken to recruit his exhausted forces."[1]

In 1843, a work was produced at Louisville by Dr. W. A. M'Dowell, styled a "Demonstration of the Curability of Consumption in all its stages;" and the same year the St. Louis Medical and Surgical Journal was established by Dr. M. L. Linton. A work of great merit was also published by Dr. Gross, of the University of Louisville, entitled "An Experimental and Critical Inquiry into the Nature and Treatment of Wounds of the Intestines," the result of a series of experiments which he had performed on dogs.

In 1844, numerous works of real value appeared. The following is a list: A Treatise on the Diseases of Children, by Dr. D. Francis Condie; a quarto volume on Operative Surgery, by Dr. Joseph Pancoast; an Atlas illustrative of the structure of the human body, prepared with great care by Dr. Henry H. Smith; a treatise on the Teeth, by Dr. Paul B. Goddard and Joseph E. Parker, a practical Dentist of Philadelphia; an ingenious essay by Dr. John Harrison, of the University of Louisiana, towards a correct Theory of the Nervous System; two volumes of lectures, by the veteran teacher Dr. Nathaniel Chapman; and the American Journal of Insanity. Few physicians in our country have used their pens more industriously or more profitably than Condie, whose work on Diseases of Children was accounted, when written, the most learned and judicious that had appeared on the subject in the English

[1] O. W. Holmes, Report Med. Literature, Trans. Am. Med. Assoc., 1848.

language. The great fame of Chapman as a writer and teacher gave currency to his volumes. Dentistry, which was already making rapid progress, both as a science and an art, in our country, received a favorable impetus from the work of Goddard and Parker. The splendid work of Pancoast secured him a reputation wherever surgery was cultivated. As a guide to the practical surgeon, it was of the highest value, each operation being illustrated by drawings representing the anatomy involved.

The first work by an American, on Diseases of the Skin, appeared in 1845, and was written by Dr. N. Worcester, of the Cleveland Medical College. Other valuable works were issued at the same time, one of which was a volume of essays on Pathology and Therapeutics, by Dr. Samuel H. Dickson of the Medical College of South Carolina, one of the most accomplished of American authors.[1] Another addition was also made this year by a western teacher of medicine to our works on Materia Medica; Dr. John P. Harrison, of the Medical College of Ohio, wrote a treatise on that subject in two volumes, earnestly inculcating "Solidism." "In the discussion of the action of medicines, we have endeavored," he says, "to place the whole question on a footing conclusively vital." He discusses blood-letting at great length. His classification is recommended by its simplicity, all his remedies being embraced in six classes. The work is written in a diffuse style, and was recommended more by its judicious therapeutics than by its scientific teachings.

A volume of Lectures, by Dr. Chapman; a work on Fevers, by Dr. Meredith Clymer; a treatise on Scrofula, by Dr. Phillips; the Young Stethoscopist, by Dr. H. I. Bowditch; an Epitome of the writings of Hippocrates and Galen, prepared by Dr. John Redman Coxe; a valuable memoir by Prof. Robert Peter, containing an analysis of the calculi in the museum of Transylvania University, with remarks on the relative frequency of calculous affections at Lexington, and the probable causes; and First Principles of Chemistry, by Prof. Benjamin Silliman, Jr., who was fast succeeding to the fame of his father, were some of the contributions to our literature in 1846.[2] Dr. Lewis C. Beck, in 1846, wrote on the Adulteration of various substances used in Medicine and the Arts, with the means of detection; and a practical Treatise on Ventilation was also published by Dr. Morrill Wyman.

The discovery of anæsthesia renders this year memorable in the history of our profession. Towards its close, Dr. Henry J. Bigelow read before the Boston Medical Improvement Society, a paper in which he detailed the facts concerning the great event that had fallen under his observation, and vouching for the efficacy of sulphuric ether in annulling pain in surgical operations. This first communication on the subject appeared in the Boston Medical and Surgical Journal, Nov. 18, 1846, and is noteworthy as announcing to the world one of the noblest discoveries in Medicine.

[1] Dr. G. R. B. Horner added an interesting volume on the Medical Topography of Brazil and Uruguay, and Dr. Stephen W. Williams contributed one on the Medical Biography of the United States. The Buffalo Medical and Surgical Journal, under the able editorial direction of Dr. Austin Flint, was established. Dr. Horner had in 1839 published a work on the Mediterranean, and in 1854 he contributed one on the diseases and injuries of seamen. Dr. J. H. Griscom published in 1845 an instructive little work on the Sanitary condition of the laboring Population of New York.

[2] Dr. Peter also contributed to Medical Science by his Analysis of the Mineral Springs of Kentucky, contained in the geological reports of that State.

The meeting of physicians at New York, which resulted in the organization of the American Medical Association, is another event of this year, which marks an era in the history of Medicine in the western hemisphere. The effect of the Association upon the profession has been in every way beneficent, elevating its tone, promoting harmony among its members, and stimulating and improving its literature. Few movements of the century to which these papers refer have contributed so much to the advancement of American Medicine.

Dr. Horace Green, in 1846, startled the profession by a work on the Diseases of the Throat and Air-passages, proposing to introduce remedies into the larynx; but his bold practice has been justified by subsequent experience, and he is now admitted to have been a pioneer in this department of medicine, and to have led the way to what others with better instruments have accomplished.

Numerous works apeared in 1847, conspicuous among which was the learned treatise of Dr. George B. Wood on the Practice of Medicine. It had the advantage over all its predecessors in that department, of being founded on clinical observation, and as a consequence was soon adopted as the text-book in our schools, and became the popular work of reference with practitioners. Dr. Charles D. Meigs issued another of his works, written in his peculiar, somewhat fantastic style—his "Woman; her Diseases and Remedies," with the effect of increasing the growing interest of the profession in Gynæcology. Dr. Joseph Carson commenced the issue of a series of colored "Illustrations of Medical Botany," and Dr. R. Eglesfeld Griffith produced a practical volume on the same subject. A most valuable contribution was made to pathological anatomy by Dr. J. B. S. Jackson, in his Descriptive Catalogue of the Anatomical Museum of the Boston Society for Medical Improvement. In 1847 Dr. David H. Tucker produced a small volume entitled Elements of the Principles and Practice of Midwifery.[1]

In 1848, a volume of Transactions was issued at Baltimore by the American Medical Association, which had been organized at Philadelphia the year before. A volume has been sent out by the Association annually since, and while it would be easy to point out defects in them all, it will not be denied by any unprejudiced reader that they form a valuable body of medical literature. All that comes before each meeting, or nearly all, appears in the Transactions, and it follows that much is published which if submitted to a rigid criticism would never see the light. But the series embraces many strong, original, and truly valuable papers from the best minds in the profession, and, apart from the diffusion of knowledge thence directly resulting, the effect of inviting physicians everywhere to write for the Association has been to develop and improve professional talent in a way that nothing but such a society could have done.

The following works also came out in 1848: A volume by Dr. Alfred Stillé, on General Pathology, which possessed great merit, both as to its

[1] Dr. H. H. Smith also published this year a Minor Surgery; and Dr. Edward Jarvis contributed a treatise on Physiology for the Use of Schools and Families. Dr. J. W. Francis delivered an admirable anniversary address before the New York Academy of Medicine, which was published; Dr. John Ware published an able address on Medical Education. "Water versus Hydropathy" appeared, a practical essay on Water in its relations to Medicine, by Dr. Henry Hartshorne. Dr. John Neill published Outlines of the Veins and Lymphatics; and Dr. J. J. Reese a small work on Physiology. The Dental Register of the West also came out this year.

matter and the style of its execution; a practical and excellent Treatise on the Diseases of Children, by Dr. J. Forsyth Meigs; the learned lectures on the Theory and Practice of Physic, of Drs. Bell and Stokes; a treatise on Etherization, by Dr. Walter Channing, embodying his experience of anæsthesia in midwifery; a work of much originality on Croup, by Dr. Horace Green; the ingenious essay on the Cryptogamous Origin of Diseases, by Dr. J. K. Mitchell, a man of genius as well as of learning and large experience; a posthumous volume on Surgery, by the gifted Dr. George McClellan, of the Jefferson Medical College, edited by his son, Dr. J. H. B. McClellan; Observations on Diseases of the Chest, and on Auscultation, by Dr. Blakiston; Dr. Pliny Earle's interesting history of the Bloomingdale Asylum for the insane; and two new journals of Medicine, the Charleston Medical Journal and the Northwestern Medical and Surgical Journal.[1]

The additions to our literature in 1849 were hardly less numerous than those of the preceding year. Dr. Meigs produced a treatise on Obstetrics; and one on the same subject appeared from the pen of Dr. Henry Miller, of the University of Louisville. Both works possessed great merit, as the productions of independent, vigorous minds long turned upon that branch of medicine. Dr. E. D. Fenner issued a volume of Southern Medical Reports, full of original observations on the diseases of the Southern States, which was followed by a second volume in 1851. Dr. Worthington Hooker produced his "Physician and Patient," presenting a sensible view of the mutual duties, relations, and interests of the medical profession and the community; and Dr. J. W. Powell contributed a work on the eye and its diseases. Equal in merit to any of these, and superior to most, was a volume of Essays, by Dr. John B. Beck, on Infantile Therapeutics, to which are added observations on ergot, and an interesting account of the origin of the use of mercury in inflammatory complaints.[2]

The contributions of 1850 embrace some of the ablest made to our literature by the American medical profession. They are the following: a Treatise on the Diseases of the Great Interior Valley of North America, by Dr. Daniel Drake; Observations on certain of the Diseases of Young Children, by Dr. C. D. Meigs; a work on Materia Medica and Therapeutics, by Dr. Thomas D. Mitchell; the Principles of Medical Jurisprudence, by Amos Dean, Esq., of the Albany Medical College; a work on the Diagnosis and Pathology of Renal diseases, by Dr. Charles Frick; a History of Medical Education and Institutions in the United States, by

[1] A small volume on Etherization, with surgical remarks, by Dr. John C. Warren, was contributed to the literature of that subject: and an absurd work, by Dr. J. W. Hood, of Kentucky, was issued setting forth a theory that all abdominal diseases are caused by displacement of the abdominal organs, and curable by pads, trusses, and supporters. In addition to these, the following also appeared that year: a small volume on Bandaging and other operations in Minor Surgery, by Dr. F. W. Sargent; a Compendium of the various branches of medical science, by Drs. J. Neill and F. G. Smith; a Handbook of Surgery, by Dr. J. Neill; Lectures on Yellow Fever, by Dr. John Hastings, U. S. A.; a Medical Chemistry for the use of Students, by Dr. D. P. Gardner; an essay on epidemic meningitis, by Dr. S. Ames; and a dictionary of dental surgery and medical terminology, by Dr. Chapin Harris.

[2] The following also appeared in 1849: a small volume on Epidemic Cholera, by Dr. C. B. Coventry; a Treatise on the Diseases of the South, by Dr. G. McGowan; Surgical Essays and Cases, by Dr. D. L. Rogers; and an Essay on Respiration and its effects, by Dr. E. Willard. The Transylvania Journal of Medicine, which had been discontinued, was revived by Dr. Ethelbert L. Dudley for a short time. A paper on Aneurism, by his illustrious uncle, Dr. B. W. Dudley, enriched one of the early numbers of the journal.

Dr. N. S. Davis; a work on the Practice of Surgery, by Dr. J. Hastings; a work on Mental Hygiene, by Dr. Wm. Sweetzer; a Practical Treatise on the Diseases and Injuries of the Urinary Bladder, by Dr. Samuel D. Gross; and a work on Sleep, psychologically considered, with reference to Sensation and Memory, by Dr. B. Fosgate. To this long list must be added a history of Typhoid Fever, as it appeared in Georgetown, Kentucky, by Dr. W. L. Sutton; the American Medical Formulary, by Dr. J. J. Reese; an Encyclopædia of Chemistry, by Dr. Jas. C. Booth; and a treatise by Dr. Thomas E. Bond, on Dental Medicine, which is a compendium of Medical Science as connected with the study of Dental Surgery. In the same year four medical journals were started: the New Hampshire Journal of Medicine, at Concord, edited by Dr. H. Parker; the Western Medico-Chirurgical Journal, at Keokuk, edited by Drs. J. F. Sandford and S. G. Armor; the Stethoscope and Virginia Medical Gazette, at Richmond, edited by Dr. F. C. Gooch; and the Nashville Journal of Medicine and Surgery, edited by Dr. W. K. Bowling.

This list embraces several works of great labor and uncommon merit. The Observations of Meigs, like all his other contributions to Medical Science, abound in original views, at the same time practical and judicious. The work of Sweetzer is suggestive and ingenious; that of Gross, elaborate and exhaustive; but foremost among them all, in research, in breadth of scientific view, and in the wide scope of observations recorded, is the treatise of Drake. The author had planned his work when a young physician, even before taking his degree in Medicine, and had been collecting materials for its composition during the term of an ordinary lifetime. It is not made up, as so many books in all ages have been, of matter borrowed from other books, but of facts collected by himself, in a long experience, during protracted journeys, and from original observers. In the accomplishment of his design he traversed the whole Mississippi Valley, tracing the causes of its diseases from the Northern Lakes to Cape Sable. He sought to indicate in his treatise whatever there was that was distinctive in the complaints of the region of which he was writing, as induced by climate, race, mode of living, and the other agencies that modify disease. The result of his extended researches was given in two ample volumes, the second of which was published in 1854, two years after his death. That in every sense the production is a great one, has been conceded by all writers who have noticed the work; and yet it never acquired general popularity, and is now comparatively disregarded. A quarter of a century has passed away since it appeared, and no second edition has been called for by the profession. It is not of a form to be used as a text-book by students, and it must be owned that it is not quite suited to the practitioner as a book of reference. But it is a vast repository of facts, upon which all future writers must hereafter draw who would give an account of the climate, topography, and diseases of the great valley to which it relates. It can hardly be doubted that it belongs to a class of works, once described by Dr. Drake himself, that "lie embalmed in the truths with which they are penetrated, and cannot decay: but like the bodies of kings and philosophers steeped in spices, and deposited in the catacombs, are found only in unfrequented closets and alcoves of libraries."

The most important works published in 1851 were a volume of lectures on Materia Medica, by Dr. John B. Beck, prepared for the press after his death, by his friend, Dr. R. C. Gilman; and a system of Operative Surgery, by Dr. H. H. Smith, based on the practice of the surgeons of

the United States, and comprising a bibliographical index and historical record of many of their operations during a period of two hundred years. Besides these, a history of the Massachusetts General Hospital was contributed by Dr. N. O. Bowditch.[1] Dr. M. L. Linton, of the University of St. Louis, also made this year a contribution which is worthy of notice, his Outlines of General Pathology; an unpretending little volume, but abounding in sound medical philosophy, and written in a lucid, vigorous style.

Dr. Austin Flint, in 1852, commenced a series of publications, the result of his observations of disease in hospitals and private practice, which have placed him at the head of American writers on practical medicine. That year he issued a volume of Clinical Reports on Continued fever, based on an analysis of 164 cases. The same year, Dr. R. U. Piper published an elaborate work on Operative Surgery, containing more than 1900 engravings, with explanatory text; to which is appended an interesting chapter on the use of Ether in Surgery, written by Dr. Henry J. Bigelow. This year, too, was produced a volume of essays written in a charming style, by Dr. S. H. Dickson, on Life, Sleep, and Pain.[2]

Dr. William H. Boling, of Alabama, whose various articles on malarious fevers in the periodicals of the day had given him a wide reputation, published, in 1853, an instructive essay on the mechanism and management in Parturition of shoulder presentment. In the same year Dr. Joseph Warrington contributed an Obstetric Catechism, containing 2347 questions and answers on obstetrics proper. Dr. C. E. Brown-Séquard commenced in 1853 a series of publications of great interest to physiologists and practitioners. The first was a small volume of experimental researches applied to physiology and pathology. A smaller volume followed in 1855, on the physiology and pathology of the spinal cord; and in 1857 another thin volume appeared, entitled Researches on Epilepsy. In 1860 he published a volume of Lectures on the Physiology and Pathology of the Central Nervous System, delivered at the Royal College of Surgeons of England; and in 1868 this was followed by another volume of Lectures on the Diagnosis and Treatment of functional nervous affections.

In 1854, a volume of substantial merit was produced by Dr. René La Roche, the title of which describes its character: Pneumonia, its supposed connection, pathological and etiological, with autumnal fevers, including an inquiry into the existence and morbid agency of malaria. It is a monograph of enduring interest. Other works that enriched our literature also appeared in that year, among which the following are

[1] Dr. Charles Delevy wrote De la Fièvre pernicieuse de la Nouvelle Orléans, following this history, in 1859, with a Précis historique de la Fièvre. Dr. F. B. Flagg published a work on Ether and Chloroform.

[2] The following works were also published: A Treatise on Diseases of the Chest, by Dr. John A. Swett; Records of Maculated Typhus, or Ship Fever, by Dr. J. B. Upham; a Treatise on Uterine Displacements, by Dr. W. E. Cole; Analysis of Physiology, by Dr. J. J. Reese; Outlines of the Arteries, by Dr. John Neill; and a description of a skeleton of the mastodon giganteus, by the veteran anatomist and surgeon, Dr. John C. Warren. Dr. A. Clapp, of New Albany, a man of great attainments in general science as well as in medicine, contributed a valuable synopsis or systematic catalogue of the medicinal plants of the United States, to the American Medical Association, which appeared in its Transactions for that year, and was afterwards issued in a separate volume of more than 200 pages. In 1852 two periodicals were published in New Orleans—the New Orleans Medical Journal, and the Monthly Medical Register. Since the war, the former has been revived, and is ably conducted by Dr. Samuel M. Bemiss.

conspicuous: a treatise, by Dr. Gross, full and exhaustive, on Foreign Bodies in the Air Passages; Dr. T. G. Richardson's Elements of Human Anatomy, in which the author, as far as he could, has substituted English for the Latin terminology—a manual admirably adapted to the dissecting room; Dr. Bennett Dowler's "Tableau of Yellow Fever" as it prevailed in New Orleans in 1853, with topographical, chronological, and historical sketches of the epidemics of that city since their origin in 1796; and a history of the yellow fever of 1853, in New Orleans, by Dr. E. D. Fenner.[1] Dr. Meigs also added to his other valuable works, this year, a volume written with great force, on the nature, signs, and treatment of childbed fevers, contending against their transmission by contact. And Dr. Jacob Bigelow laid the profession under additional obligation by a volume entitled "Nature in Disease, illustrated in various discourses and Essays," recommending by conclusive arguments the conservative medicine, toward which the professional mind of the age is so strongly tending. A volume was published in 1854, by Dr. A. S. Piggott, entitled Dental Chemistry and Metallurgy, which was of much use to practitioners of Dentistry.

The publications of 1855 were, many of them, of very great excellence and interest. The Letters of Dr. James Jackson to a Young Physician, in a small volume, to which he added a second series in 1860, are adapted to the wants of the inexperienced of every age, and may be read with profit by all young practitioners. A small work, by Dr. Hugh L. Hodge, on criminal abortion, discusses a subject, the interest of which is likely to increase with time. The treatise on Medical Jurisprudence, by Francis Wharton, Esq., and Dr. Moreton Stillé, stands on a level with the great work of Beck. The joint production of a learned jurist and an able physician, it possesses merits not likely to be found in a work by a single hand. It is a noble monument to the memory of its medical contributor, who died almost at the moment when the last sheets of his work were issuing from the press. Gifted, cultivated, and laborious, Stillé, in his short life, accomplished a work of which his profession is justly proud, and which only increases the regret at his early death. The monograph on the Diseases affecting the Respiratory Organs, by Dr. Flint, was in the line of his work on Continued Fever, and worthy of it. The tract of Dr. O. W. Holmes, entitled Puerperal Fever as a Private Pestilence, presents strong reasons for believing in the contagiousness of the disease. It was pronounced by Ramsbotham, when it came out, "a masterly performance." Dr. Zina Pitcher, in a paper on the Induction of Puerperal Fever by Inoculation, so called, takes the opposite side of the question, which he supports by a great array of facts. An Army Meteorological Register, for twelve years, originating from an office suggested by Hon. J. C. Calhoun, while Secretary of War, and prepared under the direction of Surgeon-General Thomas Lawson, is of value. Dr. E. R. Peaslee wrote this year a valuable work on Croup, and a work for students on Chemistry was issued by Dr. B. Howard Rand.

But the great work of this year was that on Yellow Fever, by Dr. La Roche. The American press has given birth to no original work superior to it in research or learning. As a monograph on one of the most

[1] To this list must be added a text-book of Anatomy, for the use especially of students of Dental Surgery, by Dr. R. Handy, of the Dental College of Baltimore; a volume of Lectures on pulmonary consumption, by Dr. T. Thompson; Letters on Yellow Fever, Cholera, and Quarantine, by A. F. Vaché; and a work on Human Physiology, by Dr. Worthington Hooker, designed for Colleges and general reading.

formidable of the epidemics that afflict our race, it may be doubted whether anything more exhaustive is contained in any language. It was the production of a laborious student, a thorough medical scholar, and an amiable and accomplished gentleman.

In 1855, the Atlanta Medical and Surgical Journal, under the care of Drs. Westmoreland and Batty, was set on foot, and in the same year a History of the American Medical Association was written by Dr. N. S. Davis.[1]

The following year was also productive of valuable additions to the stock of our literature. Professor Edward Parrish, of the Philadelphia College of Pharmacy, wrote an introduction to practical pharmacy, which was useful in that department of medicine; an original and most able work on Human Physiology, statistical and dynamical, was contributed by Dr. John W. Draper, who before had written a remarkable treatise on the forces which produce the organization of plants, in which he proposed a simple and ingenious theory of the capillary circulation. Dr. George B. Wood communicated the results of his matured researches concerning medicines, in his able treatise on Therapeutics and Pharmacology, or Materia Medica, which has long been an authority in the profession. A prize essay of great interest was published by Dr. George H. Lyman, giving the history and statistics of Ovariotomy, and the circumstances under which the operation may be regarded as safe and expedient. A Treatise on Surgery, the result of much labor, by Dr. H. H. Smith, was added to our literature on that subject. A history of the medical profession in ancient times was contributed by Dr. John Watson. Dr. James Stewart produced a practical treatise on the Diseases of Children. Dr. Isaac Taylor, in a short paper, called the attention of the profession to the sun-burnt appearance of the skin as an early diagnostic symptom of supra-renal capsule disease. Dr. J. M. Allen added another to the list of our anatomical works, in his Practical Anatomist. The North American Medico-Chirurgical Review, which originated in Louisville, but was shortly afterward transferred to Philadelphia, was added by Drs. Gross and Richardson to our long list of medical journals.[2]

The question of the original unity of the human race has been a good deal discussed in our country since the appearance of Dr. S. S. Smith's work on the subject, and in 1857 a treatise of much bulk and labor was contributed by Drs. Nott and Gliddon, On the Indigenous Races of the Earth, of the merits of which various opinions have been expressed, according to the preconceived notions of the writers. Dr. E. R. Peaslee in this year published a work on Human Histology, to which, in 1872, he added one of great interest, on Ovarian Tumors. Dr. Paul F. Eve did the profession a service by collecting into a volume many Remarkable Cases in Surgery, showing into what errors surgeons of experience and

[1] An Essay on Malignant Cholera, by Dr. B. M. Byrne; the Practitioner's Pharmacopœia, by Dr. J. Foote; a Discourse, by Dr. J. H. Griscom, on the relation between the people and the Science of Medicine; and a volume, by Drs. Comstock and Comings, on Physiology, chiefly taken without acknowledgment from the writings of Carpenter, were also among the publications of 1855.

[2] Dr. Joseph Jones published in this year some investigations relative to American Vertebrata; and Dr. M. L. Knapp wrote an interesting inquiry into the cause of Nurse's Sore Mouth, and in the following year produced a rambling treatise, styled Researches as to the Pathology and Origin of Epidemics, tracing all to the existence of a scorbutic taint. Dr. Benjamin Haskell also published this year some ingenious Essays on the physiology of the nervous system, with an appendix on hydrophobia, and the Medical and Surgical Reporter, under the editorial care of Dr. S. W. Butler, took its place among our periodicals.

skill may fall, and under what extremities patients may sometimes recover. This year, also, was published an interesting Catalogue of Crania, by Dr. J. Aitken Meigs. But a more important contribution to our literature was made by Dr. H. F. Campbell, in an essay to which a prize was awarded by the American Medical Association, On the Excito-Secretory System of Nerves. In the views advanced on this subject, Dr. Marshall Hall admitted that Dr. C. had anticipated him, as well as M. Claude Bernard.

The succeeding year two large octavo volumes on Materia Medica, full of useful matter, were issued by Dr. William Tully; a text-book on vegetable and animal physiology was produced by Dr. H. Goadby, and an interesting monograph on Scarlatina, by Dr. Caspar Morris, appeared in a new dress, having been first issued some years before; a work, too, on the diseases of the urinary organs, which was followed by one, in 1861, on the effects of the retention of the elements of urine in the blood, was published by Dr. W. W. Morland.[1] A volume of lectures on Surgery, delivered by Prof. E. Geddings, of the Medical College of Charleston, was published in 1858. It is to be regretted that the learned and able author has not followed up his work.

In 1859, the treatise of Dr. John C. Dalton, on Physiology, which still maintains its place as a text-book in our schools, was published, and is not likely to be soon superseded. It is a work which has advanced physiological science, and in which the student finds a condensed but lucid summary of its truths, communicated in a pleasing style. With it appeared another work which has conferred lustre upon the medical literature of our country, the learned and able System of Surgery, by Dr. Samuel D. Gross. With an industry truly indefatigable, the author has continued to add to its successive editions, until he has made it one of the most thorough systems of surgery to be found in any language. Dr. Austin Flint, the same year, produced a practical treatise on the Diseases of the Heart, which ranks among the high authorities on that subject.

A volume of essays, written by his gifted father, was published this year by Dr. S. Weir Mitchell. In these essays, the author appears as a chemist and philosopher, and shows that, if he had continued his labors, so successfully begun in that direction, he might have attained a high rank among the scientific men of his time. His researches concerning the diffusion of gases gave him a glimpse of some of the most interesting discoveries of which modern chemistry can boast.[2]

In 1860 a number of excellent books were produced, foremost of which in research and learning, as well as in size, is the treatise of Dr. Alfred Stillé, on Therapeutics and Materia Medica. Of the progress of our medi-

[1] Valuable contributions to operative surgery and surgical pathology were made this year by Dr. J. M. Carnochan, and Dr. Horace Green published selections from favorite prescriptions of living American practitioners. The following journals were set on foot in 1858: The Chicago Medical Journal, by Dr. J. Adams Allen; the Cincinnati Lancet and Observer, by Dr E. B. Stevens; and the Cincinnati Medical News, by Dr. J. A. Thacker. A little work was also published by Dr. Jacob Bigelow, entitled Brief Expositions of Practical Midwifery, to which is prefixed the Paradise of Doctors.

[2] Dr. E. J. Coxe wrote, this year, on the Yellow Fever of New Orleans; Dr. V. M. Francis published a Thesis on Hospital Hygiene, and a work styled Contributions to Midwifery; the Diseases of Children was issued by Drs. Noeggerath and Jacobi; Dr. J. J. Moorman wrote an account of the Virginia Springs and the Springs of the South-West, which was of great value to invalids in search of watering-places. A small treatise was published by Dr. John M. Watson, of the University of Nashville, on trismus nascentium, which he traces to irritation of the umbilicus in the young child. Dr. James E. Reeves, the same year, published a Practical Treatise on Enteric Fever.

cal literature during the century, we could hardly point to any evidence more conclusive than that afforded by a comparison of this scientific work with the elementary treatises on the same subject written forty years before. We are quite willing that by it the world shall judge of American Medical authorship. The "Practical Treatise on Fractures and Dislocations," by Dr. Frank Hastings Hamilton, has become a standard authority on the subject.[1] An Elementary Treatise on Anatomy was prepared by the learned Professor of Anatomy in the University of Pennsylvania, Dr. Joseph Leidy. Dr. Henry Hartshorne published "Memoranda Medica," or note-book of medical principles. A very instructive work was issued by Dr. Hugh L. Hodge, on the diseases peculiar to females, including displacements of the uterus. And among the "Contributions" of the Smithsonian Institution appeared an original paper of much interest, by Dr. S. Weir Mitchell, on the venom of the rattlesnake.[2]

Of the publications of 1861, the most important was a work on the principles and practice of Obstetrics, by Dr. Gunning S. Bedford, of the University of New York. But the American Medical Biography, edited by Dr. Samuel D. Gross, has also high claims upon the profession, and ought to be extended. It is a work which must be of interest to every American physician, as a record of the lives of men who have done honor to the profession. Dr. Gross, the same year, produced an excellent manual of military surgery. A "Manual of Military Surgery," was also produced by Dr. J. Julian Chisholm, at Columbia, South Carolina, and was the text-book of the surgeons of the Confederate army during the civil war. And one on the same subject was contributed by Drs. Blackman and Tripler.[3]

The effect of the civil war in repressing our literature, was manifest in 1862, in the course of which very few original books were published. One of these was the Medical History of the Philadelphia Almshouse, by Dr. D. Hayes Agnew; a second was a treatise, by Dr. A. Jacobi, on dentition and its derangements; and a third was a practical guide to diseases of the eye, by Dr. H. W. Williams. Dr. Stephen Smith added an opportune hand-book on surgical operations.

In 1863, the number was also small. They were a Manual of the institutes of military surgery, by Dr. J. Ordronaux; a manual of minor surgery, by Dr. J. H. Packard, and the practice of surgery for field and hospital, by Dr. E. Warren. Dr. J. J. Woodward made a practical and substantial contribution to military medicine, in a volume on the chief

[1] A useful medico-legal treatise on Malpractice was written by Dr. John J. Elwell. Dr. Samuel W. Francis presented to the profession a report of the Clinical Lectures of Dr. Valentine Mott in the University of New York.

[2] A Catalogue of the Pathological Cabinet of New York Hospital, classified and arranged, was published this year by Dr. Robert Ray, Jr., and also an epitome of medicine and surgery, by Dr. W. S. Wells. Dr. Edward Warren, in 1860, published an interesting biography of Dr. John C. Warren. Two new medical journals were also projected: the Pacific Medical and Surgical Journal, edited by Dr. Henry Gibbons, and the Chicago Medical Examiner, edited by Drs. N. S. and F. H. Davis.

[3] Besides these, the following works also appeared in 1861: A Practical Treatise on Phthisis Pulmonalis, by Dr. L. M. Lawson, of Cincinnati; a work by Dr. R. M. Hodges, on Excision of the Joints; one by C. H. Jackson, on Etherization; a sprightly paper on Currents and Counter-currents in Medical Science, by Dr. O. W. Holmes; a work on Placenta Prævia, by Dr. William Reid; and two valuable Essays, by Dr. Fordyce Barker, one on an Effort to shorten the first stage of Labor; the other on the use of anæsthetics in Midwifery. Dr. Edwin R. Maxson also published this year a volume on the Practice of Medicine, and, in 1868, he published an account of Hospitals, British, French, and American.

camp diseases of the U. S. armies as observed during the war of the rebellion.

In 1864, an important work on Gunshot Wounds and Injuries of Nerves was contributed by Dr. S. Weir Mitchell and Drs. Morehouse and Keen; and in this year the following works also appeared: Lectures on Venereal Diseases, by Dr. William A. Hammond; a Medical Dictionary, by Dr. J. Thomas; a paper on the puerperal disease, by Dr. B. F. Barker; a work by Dr. Bartholow on disinfection, which was followed in 1867 by a manual on enlisting and discharging Soldiers, and in 1868 by a work on spermatorrhœa; a prize-essay by Dr. H. F. Damon, on leucocythæmia; a volume of Medical and Surgical Essays, by Dr. W. A. Hammond; a "Mémoire sur la fièvre paludienne," by Dr. J. C. Faget; and an account, by Dr. J. O'Reilly, of the Nervous and venous connection between the Mother and the Fœtus.

The following is a list of the publications in 1865: a Monograph on glycerin, by Dr. H. Hartshorne; the Book of Prescriptions, by Dr. Henry Beasley; a Treatise on Military Surgery and Hygiene, by Dr. F. H. Hamilton; a Vest-pocket Medical Lexicon, by Dr. D. B. St. John Roosa; a Treatise on the Diseases and Accidents incident to Women, by Dr. W. H. Byford; and Elements of Materia Medica for the use of students, by Dr. John B. Biddle. The last two are substantial additions to our practical medical literature. No more eligible text-book than Dr. Biddle's has yet been written; and the volume by Dr. Byford illustrates a class of affections which he has studied with success. To this list we have to add the able work of Dr. W. H. Van Buren on the Surgical Diseases of the Genito-Urinary Organs, and his contributions to Practical Surgery; and the Lectures of Dr. J. H. Packard on inflammation.[1]

Cholera prevailed in the United States in 1866, and a number of works were written concerning the epidemic; but besides these, that year was productive of some of the best contributions made by American writers to medical science. The work of Dr. Austin Flint, on the Principles and Practice of Medicine, is entitled to the first place among our treatises on that subject. It is the production of a practical, able, and patient observer, who speaks from long clinical experience, and is written in a clear, direct, concise style, and with a fulness that leaves nothing to be desired. And by the side of this admirable work deserves to stand the treatise of Dr. Austin Flint, Jr., on Physiology, the first volume of which appeared about the same time, and which has since been completed in five volumes. Few works of equal merit to these, the productions of father and son, have proceeded from American authors. Another publication of that year possessing great value was the treatise of Dr. J. M. Da Costa, on Medical Diagnosis, a work with which our students of medicine can hardly dispense; and one of equal value to the practitioner was that of Dr. J. Marion Sims, entitled Clinical Notes on Uterine Surgery, with special reference to the sterile condition; the first treatise written in our language on the surgery of the uterus.[2]

[1] In this year the following works too appeared: A Sanitary Code for Cities, by Dr. H. G. Clarke; a volume on Hypodermic Injections, by Dr. Antoine Ruppaner; and the New York Medical Journal, edited at first by Dr. W. A. Hammond, and subsequently by Drs. J. B. Hunter and W. T. Lusk.

[2] A treatise appeared, this year, by Dr. J. W. Wright, on Psychology, and one by Dr. S. G. Webber, on cerebro-spinal meningitis. Dr. A. C. Garratt also contributed one on electro-therapeutics, and three new journals of medicine were projected—the Detroit Review of Medicine, by Drs. Conner and Lyons; the New York Medical Record, by Dr. Geo. F. Shrady,

Dr. Henry Hartshorne in 1867 produced a volume which has met with much professional approbation, entitled Essentials of the Principles and Practice of Medicine. A very able work of an original character, on the micro-chemistry of poisons, was produced by Dr. Theo. G. Wormley. Dr. J. Solis Cohen contributed a valuable volume on Inhalation, its therapeutics and practice. One was produced on injuries of the Spine, by Dr. John Ashhurst, Jr., containing an analysis of nearly four hundred cases. Drs. Francis Minot and Charles Homans, Secretaries of the Society, published a volume of Extracts from the Transactions of the Boston Society for Medical Improvement, with Papers read before the Society. The lamented Dr. J. Mason Warren contributed a valuable volume of Surgical Observations, with Cases and Operations. Dr. N. R. Smith wrote on the treatment of fractures of the lower extremities, by the use of the anterior suspensory apparatus; and Dr. John H. Packard published Notes on Fractures of the Upper Extremity. A volume of Researches upon Spurious Vaccination was contributed by Dr. Joseph E. Jones. Dr. Henry J. Bigelow published a practical paper on Ununited Fractures successfully treated; and Dr. B. Howard Rand contributed an elementary work on Chemistry. A work of much labor was issued under the editorial supervision of Dr. A. Flint, entitled Contributions relating to the Causation and Prevention of Disease, and to Camp Diseases, together with a report of the diseases, etc., among the prisoners at Andersonville. A large volume, entitled Mechanical Therapeutics, a treatise on surgical appliances, was produced by Dr. Philip S. Wales, at Philadelphia. A Monograph on Cerebro-Spinal Meningitis, treating ably of the subject, was issued by Dr. Alfred Stillé. Dr. S. H. Dickson made a valuable contribution to Studies in Pathology and Therapeutics; and an interesting work on the Medical Use of Electricity was produced by Drs. George M. Beard and A. D. Rockwell. To which long catalogue of publications for that year we have to add the Leavenworth Medical Herald, by Dr. Tiffen Sinks, and the Medical Archives, by Dr. J. C. Whitehill, published at St. Louis.[1]

In 1868 three important works were produced on the diseases and accidents incident to females; an Obstetric Clinic, by Dr. George T. Elliot; a Practical Treatise on the Diseases of Women, by Dr. T. Gaillard Thomas; and a work on Vesico-vaginal Fistula, by Dr. Thomas Addis Emmet. Dr. Dalton wrote a Treatise on Physiology and Hygiene, for schools, families, and colleges; a volume of Reports of the Pennsylvania Hospital, was edited and issued by Dr. Da Costa and Dr. W. Hunt; and a work on Physical Diagnosis was published by Dr. Alfred Loomis.[2]

and the Richmond (now Richmond and Louisville) Medical Journal, by Dr. E. S. Gaillard, editor and proprietor. This year the following works also were published: Contributions to bone and nerve Surgery, by Dr. J. C. Nott; a small treatise on food and digestion, by Dr. Howard Townsend; Lectures on Orthopedic Surgery, by Dr. L. Bauer; a small treatise on Orthopedics, by Dr. D. Prince, followed, in 1871, by one on Plastics; and works of greater or less length on Cholera, by Drs. J. C. Peters, R. Nelson, E. Whitney, F. A. Burrall, Palmer, Fletcher, and Henry Hartshorne.

[1] Two works on conservative surgery, one by Dr. H. G. Davis, and another by Dr. A. G. Walter, appeared in 1867, and with them a Manual of Examinations, by Dr. J. L. Ludlow; a paper on Epidemic Cholera, by Dr. G. Hurt; a Treatise on Polypus of the Ear, by Dr. Edward H. Clark; a work by Dr. D. Wooster, on Diseases of the Heart, and a Thesis on Aneurism of the Aorta, by Dr. E. Souchong.

[2] Beside these the following also appeared: The Law of Human Increase, or Population based on Physiology and Psychology, by Dr. Nathan Allen; a Practical Anatomy, by Dr. D. H. Agnew, who followed it in 1873 by a work on laceration of the perineum; a Treatise, by Dr. W. Bodenhamer, on Diseases of the Rectum; a Dissertation, by Drs. Edes,

The following list comprises the most noted publications of 1869: A Treatise on the Diseases of Infancy and Childhood, by Dr. J. Lewis Smith; a Conspectus of the Medical Sciences, by Dr. H. Hartshorne; Outlines of Comparative Anatomy and Medical Zoology, by Dr. Harrison Allen; a History of the Medical Department of the University of Pennsylvania, by Dr. Joseph Carson; the Intermarriage of Relations, by Dr. Nathan Allen; a treatise, by Dr. J. S. Lambert, on Longevity; Contribution to the Medical History of the United States, by Dr. J. M. Toner; the Mechanism of Dislocation and Fracture of the Hip, by Dr. H. J. Bigelow; an essay on External Perineal Urethrotomy, by Dr. J. W. S. Gouley; a volume on the Jurisprudence of Medicine, in its relations to the law of contracts, by Dr. Ordronaux; a work, in quarto, on Amputation of the Cervix Uteri in certain cases, by Dr. Isaac E. Taylor; a compend of Materia Medica, by Dr. John C. Riley, and a volume on the physiology and pathology of the sympathetic nervous system, by Dr. Robert T. Edes. In addition to these, a small treatise was written on Veratrum Viride, by Dr. R. Amory; one on physical culture in Amherst College, was contributed by Dr. N. Allen; and one, of much greater size, on the Principles of Naval Staff Rank and its History for over half a century, by a Surgeon in the U. S. Navy. The Archives of Ophthalmology, edited by Profs. Knapp and Moos, and the Oregon Medical and Surgical Journal were projected this year.

The most important contributions in 1870, were the Surgical Memoirs of the War of the Rebellion, which when completed will form the most magnificent work pertaining to medicine that our country has produced; and the Treatise on the Theory and Practice of Obstetrics, by Dr. W. H. Byford, which stands on a level with the best of a class of works in which the profession of America is conceded to have excelled. The Lectures on the Diseases of the Rectum, by Dr. W. H. Van Buren, and the Hand-book of Operative Surgery, by Dr. J. H. Packard are valuable contributions to practical surgery; as are also the Bellevue and Charity Hospital Reports; the Medical and Surgical Reports of the Boston City Hospital, and the work of Dr. J. A. Lidell on wounds of the bloodvessels.[1]

The publications of the Surgeon General's Office were continued in 1871, and some very able works appeared with them, at the head of which professional opinion ranks the Principles and Practice of Surgery,

Hibbard, and Spare, on Nature and Time in Disease; a posthumous work on Electro-Physiology, by Dr. Morgan, edited by Dr. Hammond; and the Principles and Practice of Laryngoscopy, by Dr. A. Ruppaner. The American Journal of Obstetrics, edited by Dr. B. F. Dawson, was also added to the list of our serials.

[1] An excellent little Manual of the Urine was published by Dr. A. Flint, Jr.; and an interesting tract styled "New Facts and Remarks concerning Idiocy" was issued by Dr. Edward Seguin. The Microscopical Anatomy of the Liver was illustrated by Dr. H. D. Schmidt, in an article in the New Orleans Medical Journal, which was afterwards issued in a separate form; and a useful treatise was produced, on naval hygiene, by Dr. Joseph G. Wilson and Dr. Albert C. Gorgas; in addition to which Dr. M. Clymer published valuable notes on the physiology and pathology of the nervous system; Dr. J. C. Hutchison contributed a small treatise on physiology and hygiene; and Dr. L. H. Morgan published a system of consanguinity of the human family. The new journals set on foot in 1870 were the Clinic, at Cincinnati, by Dr. J. T. Whittaker; the Philadelphia Medical Times, edited by Dr. H. C. Wood; the Michigan University Medical Review, by Drs. Cheever, Rose, Prescott, and Frothingham; the American Journal of Syphilography, by Dr. M. H. Henry; and the American Practitioner, by Dr. David W. Yandell and Dr. Theophilus Parvin—a continuation of the Western Journal of Medicine, which was for some years conducted by Prof. Parvin at Indianapolis. The Photographic Review of Medicine and Surgery was also set on foot.

by Dr. John Ashhurst, Jr. The treatise of Dr. W. A. Hammond, on Nervous Diseases, is also a graceful addition to our professional literature, albeit his readers may not always obtain the gratifying results from remedies reported as occurring in his practice. The Report to the Surgeon General's Office of the surgical cases in the army of the United States from 1865 to 1871, is an invaluable storehouse of facts; and eminently useful also, for its statistics, is the first annual Report of the Board of Health Department of New York.[1]

In 1872, a volume was produced by Dr. S. Weir Mitchell on Injuries to the Nerves, and their consequences, which is esteemed one of the most valuable contributions to surgical science made by an American writer. An elaborate work on ovarian tumors was issued by Dr. E. R. Peaslee. Dr. Gurdon Buck illustrated lithotomy and lithotrity by a number of cases in a brief memoir on the subject. Dr. Thomas M. Markoe wrote an able treatise on diseases of the bones, and Dr. J. W. S. Gouley contributed one on the diseases of the genito-urinary organs, which has been much commended. The little volume of Dr. H. C. Wood, Jr., on Thermic Fever or Sunstroke, is scientific and practical, the production of a mind trained and adapted to philosophical investigation. With it appeared his Year Book of Therapeutics, Pharmacy, and the allied sciences. A volume of clinical lectures on various important diseases, possessing uncommon excellence, was contributed by Dr. N. S. Davis.[2] In this year also appeared the last work of the learned and indefatigable Dunglison, who had been called away from his earthly labors, leaving his History of Medicine to be completed by his son Dr. Richard J. Dunglison. This posthumous work of the great medical scholar is a fit companion of his dictionary, by which his name is destined to be transmitted to the latest

[1] A Handbook of Medical Microscopy was a seasonable contribution by Dr. Joseph G. Richardson. Three new journals appeared during the year, viz.: New Remedies, by Dr. H. C. Wood, Jr., at New York; the Kansas City Medical Journal, by E. W. Shauffler; and the Southern Medical Record, at Atlanta, by Drs. Powell and Goldsmith. Dr. B. Joy Jeffries wrote a treatise on the eye in health and disease; Dr. M. L. Holbrook produced one on parturition without pain; Dr. A. L. Gihon wrote on surgery and naval hygiene; and Dr. Joseph Jones appeared in one of his laborious memoirs, giving an account of the clinics at the Charity Hospital in New Orleans. Emergencies, and how to treat them, is the title of a manual by Dr. Joseph W. Howe, of the University of New York, which affords knowledge useful to all; and the work on Bromides, by Dr. Bartholow, was read with interest at a time when the action of these medicines was so much discussed. Internal urethrotomy was discussed in a short paper by Dr. C. H. Mastin; Dr. Allen produced another treatise bearing on vital statistics, entitled Lessons on Population, suggested by Grecian and Roman History. Dr. B. W. Neftel added one on Galvano-Therapeutics, and Drs. Beard and Rockwell brought out their work on the Medical and Surgical uses of Electricity in an enlarged form, rendering it complete as to the present state of that branch of therapeutics. The tenth edition of the Medical Students' Vade mecum, by Dr. George Mendenhall, was issued that year.

[2] The little works of Drs. Clarke and Amory on the Bromides of potassium and sodium, and Dr. Morrill Wyman on Catarrh or hay fever, are both admirable in their way. A hand-book of post-mortem examinations and of morbid anatomy, by Dr. Francis Delafield, also appeared. The attention of the profession was directed to Earth as a topical application in Surgery, by Dr. Addinell Hewson, in a work on that subject. A Clinical Manual of the Diseases of the Ear was prepared by Dr. Lawrence Turnbull. A brief account of the treatment of the Venereal Disease in the Vienna Hospitals was published by Dr. M. H. Henry. Two excellent little monographs on Diseases of the Skin, and Animal and Vegetable Parasites of the Human Skin, were issued by Dr. B. J. Jeffries; the Ten Laws of Health were illustrated by Dr. J. R. Black; and Dr. J. S. Cohen contributed a practical work on Diseases of the Throat. Dr. J. W. Richardson read a judicious paper on puerperal convulsions to the Medical Society of Tennessee; and Dr. Stephen Smith produced a volume styled Doctor in Medicine, with other papers. The Charleston Medical Journal, which for some time had been suspended, was revived this year by Drs. Porcher and Kinloch.

ages. The medical journals originated in 1872 were the Western Lancet, at San Francisco, by Drs. Trenor and Babcock; and the Sanitarian, edited by Dr. A. N. Bell, at New York.[1]

In 1873 a number of valuable works were published, prominent among which was Contributions to Surgery, by that faithful worker and accomplished medical scholar, Dr. George W. Norris. A handsome volume of superior merit on ovarian tumors was brought out by Dr. Washington L. Atlee, and Dr. John A. Lidell produced one on apolexy. A volume of clinical lectures on diseases of the nervous system swelled the contributions of Dr. W. A. Hammond to medical science. A volume of huge proportions was written by Dr. James E. Garretson on the somewhat limited subject of oral surgery, and Dr. Isaac Ray published one entitled Contributions to Mental Pathology.

In 1874, a work possessing some novel and attractive features was issued by Dr. Horatio C. Wood, Jr., on Therapeutics, Materia Medica, and Toxicology. The author devotes much more space than any previous writer has done to the physiological action of medicines, facts bearing upon which he has collected with great industry from every accessible source. This departure of Dr. Wood from the old beaten track of writers on materia medica imparts unusual interest to his pages. The other works of this year were a treatise by Dr. R. A. Gunn, on the Venereal Disease, and a small volume on Croup, by Dr. J. Solis Cohen.[2]

In 1875, an exhaustive volume was issued on the Epidemic Cholera of 1873. It was the joint production of Drs. Ely M'Clellan, J. C. Peters, J. M. Woodworth, and J. S. Billings, prepared by order of the General Government. No more thorough discussion of the etiology of cholera is to be found in any American work, and, as a whole, it will take its place with the foremost of the many volumes called forth in our country by that pestilence. The work of Dr. Loomis on the Diseases of the Respiratory Organs, notwithstanding the fulness with which the subject had been treated in earlier works, was an acceptable contribution. A volume was published by Dr. R. W. Taylor on Syphilitic Lesions of the Osseous System. Dr. C. S. Fenner contributed a work on Vision, its optical defects, and the adaptation of Spectacles. A work on pulmonary tuberculosis was brought out by Dr. Addison P. Dutcher. Dr. W. B. Atkinson issued a small but practical volume, entitled Hints in the Obstetric Procedure. Dr. James E. Reeves established, at Wheeling, a journal styled the West Virginia Medical Student. Two volumes of immense labor, made up of Statistics, medical and anthropological, of the Provost-Marshal-General's Bureau, were prepared by Dr. J. K. Baxter; and Dr. B. J. Cotting produced a volume of medical addresses.

The works issued in the first months of 1876 belong to the century we are commemorating. Of these, one was a characteristic volume of medical and surgical memoirs, by Dr. Joseph Jones, the first of an elaborate series which the author contemplates. This treats of many subjects, and

[1] Dr. H. V. W. Sweringen also added a pharmaceutical lexicon; Dr. M. A. Milland wrote a work on civil mal-practice; Dr. D. B. St. J. Roosa produced a treatise on diseases of the ear; Dr. Prince published a report on galvano-therapeutics, and Dr. Henry G. Piffard wrote a little work on urinary analysis.

[2] Besides these the following were contributed: A treatise by Dr. A. D. Williamson on diseases of the ear; one on the "breath and fetid odors," by Dr. J. W. Howe; one by Dr. E. Holden on the Sphygmograph; a manual of toxicology, by Dr. J. J. Reese, and a small volume by Dr. Thomas C. Minor on erysipelas and childbed fever. A new journal, the Virginia Monthly, was also started by Dr. L. B. Edwards, at Richmond, and one, the Medical Times, at Louisville, by Dr. E. S. Gaillard.

with a patient industry seldom shown by native writers. Dr. Austin Flint, Jr., issued a splendid volume, comprising the substance of his five volumes on physiology, intended as a text-book for students. A work on extra-uterine pregnancy was produced by Dr. John S. Parry, whose early death the profession was called on to deplore soon after the appearance of his work, giving so much proof of his ability to enrich his profession. Two works were contributed by Dr. Austin Flint, a monograph on Phthisis, and a small volume of essays on Conservative Medicine, works worthy of the fame of their admired author. Dr. Lewis A. Sayre added to the productions of the century a volume, abundantly illustrated, on orthopædic surgery and diseases of the joints, which has already been translated into more than one foreign language. A new journal, too, was added to our long list of periodicals, the Louisville Medical News, a weekly publication, edited by Dr. Richard O. Cowling and Dr. William H. Galt, writers of wit as well as learning, whose keen satire of abuses in medical schools will cause their work to be remembered as one of the most useful of its period.

This retrospect of our literature ought not to be concluded without a reference to the publications of the various medical societies of our country. The Transactions of the great National Association have been mentioned; but there are societies in nearly all the States of the Union which annually send forth volumes of greater or less bulk, containing papers of lasting interest. They began as far back as 1788, when the Medical Society of New Haven County, Conn., issued a volume of "Cases and Observations." This was followed, in 1793, by a volume from the Philadelphia College of Physicians. Massachusetts has been for seventy years sending out valuable communications through her societies. The Medical Society of the State of New York, too, has for more than half a century been making contributions to medical science. The effect of these societies, not only upon the literature, but upon the tone of the profession, is everywhere felt to have been most salutary.

The reports of the lunatic asylums, now founded in all but a few of the States, are also to be mentioned as works which have enriched our professional literature. It was a sagacious remark of the Governor of Kentucky, General Adair, in his message urging upon the legislature the establishment of an asylum at Lexington, that "the hospital would help the medical school, which would return the obligation by improving the hospital system, making discoveries in treatment." Since the day that medical men were first placed over these institutions, it is a fact conceded by all that a steady improvement has been going on, as well in the therapeutic treatment of their inmates as in their whole administration. The annual communications of Earle, Kirkbride, and others who have labored so successfully in psychological medicine, have received their full measure of applause.

As forming a voluminous branch of our literature, the introductory lectures published at the opening of the numerous schools of the country each autumn, deserve a passing notice. Many of these efforts are worthy of preservation, as the offspring of the best minds in the American profession; but others are "open to severe comment," as was remarked by Dr. Holmes thirty years ago, who then added that "turgid and extravagant attempts at eloquence, a fondness for effete Latin quotations, a parade of scholastic terms where simple ones only are called for, are the common faults of these productions."

In reviewing the literature of medicine in the United States, the first fact that will strike the mind of the reader, perhaps, is the very large proportion of the works that have emanated from the medical schools. Another that must occur to every reader is the disproportion between monographs and the manuals written for the use of students. Teachers have both greater leisure and greater facilities than others of the profession for making books, as they are also more likely to find sale for them; and they write text-books rather than monographs, because students demand them. But, in the nature of things, such productions are short lived. The manual that gives a fair view of its subject to-day, must fall short of representing it to-morrow, and yields of necessity to a later system. Mundinus, when medical science stood still, held his place as a text-book on anatomy in the medical schools of Italy two hundred years. Wistar, who stood his ground longer than any of our text-books, hardly kept his place thirty years; and as to those that have succeeded him, "clouds that rake the mountain summit" scarcely follow each other faster than they have followed one another as popular favorites.

The growth of our periodical literature has been unprecedented. In 1848, the committee on medical literature reported to the Medical Association, that the number of journals in the United States was about twenty. They had been fifty years reaching that number; but in a little more than half that time their number has been doubled. Since the origin of the first, in 1797, one hundred and ninety-five, including reprints of foreign journals, have been set on foot, of which more than fifty, counting those that relate to pharmacy and dentistry, are still in progress. In all, they have made one thousand six hundred and thirty-seven volumes, a bulk which exceeds that of our monographs and manuals. Hardly any other country in the world has projected so many in the same period, or is now sustaining so large a number. Germany and Austria together have only fifty-seven; France has but fifty-two; Great Britain has but twenty-nine; Italy thirty-one; Holland six; and Spain the same number. Most of our journals have subscribers enough to justify their publication, and to support them in a state of comparative ease, though one is dropped, from time to time, for want of patronage. They have, collectively, a large circle of readers, and tend to a wide diffusion of medical knowledge. The discoveries in any branch of medicine are at once announced by them, and carried in a little while to the door of every reading physician, by which the profession in country and city is placed on comparative equality. And besides these benefits, they increase a taste for reading, and stimulate practitioners to become writers; so that the admitted superfluity of our journalism has been beneficial to the profession, promoting activity among its members, bringing to light much useful matter, exciting greater and more general exertion.

But it cannot be denied that these benefits are secured at the expense of many countervailing evils. To the excess of this literature we are to attribute its deficiencies, which all admit to be greater than those that attach to our books. The aliment that would keep a dozen journals vigorous, divided between four times that number, is barely sufficient to keep many of them alive. The support of too many of them, mental, pecuniary, and literary, is flagrantly inadequate. Not only is their list of subscribers insufficient for anything beyond a feeble existence, but the corps of contributors is too limited to give the necessary variety to their pages. The editor in the hour of pressing need is often obliged to admit

articles which he would not hesitate to reject if he had anything better on hand. But no choice is left him. The inevitable day is coming round when the number must appear; the printer is waiting, and copy must be forthcoming.

Nor is this the only fault of our journalism attributable to its excess. The editors in too many cases devote only such odds and ends of their time to their publications as they can spare from more profitable engagements. Deriving hardly any pecuniary emolument from their journals, they are compelled to look to other employment for subsistence. Nearly all their time and thoughts are engrossed by other duties, and their editorial functions are necessarily performed in a hurried and slovenly manner. They cannot take the time to "*edit*" their publications in any true sense of that term. They have no leisure for correcting the papers sent them, and for putting them into a shape suitable for the public eye. These contributions, it is safe to say, are for the most part hurriedly written, very often by young, unpractised writers, and while presenting many grains of valuable truth, contain mixed up with them no small amount of chaff which calls for the winnowing hand of the editor. Wanting this friendly office, they appear before a critical public "with all their imperfections on their heads."

Editors are not responsible for either the facts or the opinions of their contributors, but the public has undoubtedly the right to expect that the matter composing their pages shall be free from glaring literary blunders. It has a right to insist, at least, that their own papers shall be written carefully, and with a moderate show of accuracy.

But the department in which our periodical literature stands most in need of improvement is that of critical reviews. In only a few of our journals has this office—one of the most important pertaining to journalism—been properly performed. It is not too much to say that it has been generally neglected. The articles that appear in the critical department rarely aspire to the dignity of reviews, but are, as a rule, mere bibliographical notices, written after the most cursory examination of the books in hand, and often with slight knowledge of their contents. The notices, therefore, are too generally made up of commonplace strictures or indiscriminate praise—mere vague generalities which leave the reader as much as ever in the dark as to the true character and value of the book reviewed.

Still, with all these deficiencies, and others that might be pointed out, our journalism is of a character to commend it to the respect of the profession. No one who has carefully observed its progress in the last fifty years can have a doubt that it is fast outgrowing its defects. Not only are the journals appearing in a mechanical dress more neat and pleasing to the eye, and with fewer typographical errors, but in point of style they are more scholarly than those of half a century ago. The articles are more generally practical, and the selections are almost always made from original sources. If many of them were started in the interest of medical schools (which will hardly be denied), it must be owned that their conductors have generally been observant enough of public opinion to keep that object in the background. Few of them have betrayed a narrow, partisan temper. Hardly an editor has availed himself of his station to defame his professional brethren. While many articles find their way into the journals that are not instructive—many that are carelessly written and marred by many literary blemishes—it is seldom that we meet with one that offends against decency or the proprieties of social life. Personali-

ties, as they are discountenanced by the profession, are almost universally eschewed.

It is easy to see that the rivulet which represented our literature at the beginning of the century just closed, "has swollen into a torrent, augmented into a river, expanded into a sea." When we assumed our position among the sovereignties of the earth, we could hardly point to a single original volume on medicine. We were dependent as a profession almost wholly upon our brethren of the old world for instruction. All our books were the production of foreigners; but we may now claim to be independent of the world. If by any chance we could be cut off from all intercourse with other nations, the authors of America would supply the text-books required by its students, and guides to its practitioners, in every department of the profession. Nor am I assuming too much when I assert that, as lucid exponents of the existing art and science of medicine, as trustworthy companions in the sick-room, as lights in everything relating to the practice of physic, using that term in its widest scope, the works of American physicians are up with the times, and equal to the books which come to us from abroad. And this is said in full view of the fact that in some branches of medical science we have not done our part towards its advancement, while in others we have hardly done anything at all. But whether we compare the later issues of our medical press with its earlier productions, or with analogous works by physicians of the old countries, we find cause for congratulation as to the past, and for high expectations in regard to the future.

ADDRESS ON THE PROGRESS OF MEDICAL EDUCATION IN THE UNITED STATES OF AMERICA,

DURING THE CENTURY COMMENCING IN 1776.

BY

N. S. DAVIS, A.M., M.D.,

OF CHICAGO, ILLINOIS.

From the date of the first English settlement in America, which was in 1607, to the Declaration of Independence in 1776, thirteen separate colonies had been established, embracing the Atlantic Coast from Massachusetts to Georgia inclusive, and all acknowledging allegiance to the government of Great Britain. Distributed over this wide extent of territory, there had accumulated about three millions of people, among whom there were between three and four thousand engaged in the practice of medicine. Of these, it has been estimated that not more than four hundred had received the degree of Doctor in Medicine from any medical college; and these, with but few exceptions, had received their collegiate education and honors in the medical schools of Europe. Only two medical schools had been organized in the colonies, namely, the Medical Department of the College of Philadelphia (now the Medical Department of the University of Pennsylvania), in 1765, and the Medical Department of King's (now Columbia) College, in New York, in 1768. Only fifty-one medical degrees had been conferred by both of these institutions prior to 1776, when active operations in them were suspended by the progress of war. In all the colonies there were not more than twelve or fifteen cities and towns having over five thousand inhabitants, and these were so widely separated from each other, and possessed of such limited means of communication, that attendance on a medical college, or on the meetings of medical societies, was hindered by delays and difficulties but little thought of at the present day.

The same condition of the country compelled many of those practising in the smaller and more remote settlements to unite other occupations with their practice. In the New England Colonies, the offices of physician and clergyman were often united in the same person, and in all the colonies it was common for the physician to occupy a part of his time and increase his income by agricultural labor.

Notwithstanding all the obstacles presented by the sparseness of the population, and the want of roads and means of communication, a large proportion of those engaged in practice had attended one course of medical college instruction, and had served a regular apprenticeship with some practitioner of note, before entering upon the active duties of the profession. Only three medical societies are known to have been organized during the colonial period of our history. The most important of these was the Medical Society of the State of New Jersey, which was organized in July, 1766. It appears that a few months previous to this, a society called the Philadelphia Medical Society was formed in that

city, chiefly through the influence of Dr. John Morgan, who had returned from Europe the year previous. It did not probably survive the war for Independence, and is not known to have left any permanent record of its doings. The Delaware State Medical Society was organized in 1776, and hence has a history parallel with that of the independence of the States.

In nearly all of the colonies, laws had been enacted concerning some topics of interest to the profession. Most of these laws were designed either to protect the people of the colonies from the introduction and spread of contagious diseases, from injury by ignorant and reckless midwives, or from exorbitant charges by physicians; or for the establishment of hospitals for the sick and insane. In only two of the colonies had laws been enacted to define the qualifications of physicians and surgeons, with provisions for enforcing an observance of the same. The General Assembly of New York, in 1760, ordained that "no person whatsoever shall practise as Physician or Surgeon in the City of New York before he shall have been examined in Physic and Surgery, and approved of and admitted by one of His Majesty's Council, the Judges of the Superior Court, the King's Attorney-General, and the Mayor of the City of New York for the time being, or by any three or more of them, taking to their assistance for such examination such proper person or persons as they in their discretion shall see fit." Such candidates as were approved received certificates conferring the right to practise physic or surgery, or both, throughout the whole province; and a penalty of five pounds was prescribed for all violations of this law.[1] A similar act was passed by the General Assembly of New Jersey in 1772.

Although most of the colonies had provided temporary hospitals for seamen, emigrants, and the victims of smallpox and other epidemic diseases, the only permanent general hospital for the sick was established in Philadelphia, in 1752, and was aided by a grant of two thousand pounds from the Colonial Assembly. Dr. Thomas Bond was appointed superintendent, with Drs. Lloyd Zachary, Thomas Cadwalader, Samuel P. Moore, John Redman and Phineas Bond, as associates.

Dr. Thomas Bond, from the opening of the institution, introduced his class of students for bedside instruction, and thereby became the first regular clinical lecturer in America. In 1767, the colonial government of New York was induced to grant a charter for a general hospital, and an organization was effected, and the work commenced. But the building when nearly completed was destroyed by fire, in 1772, and owing to the supervention of the Revolutionary war was not rebuilt until 1791. From this very brief glance at the condition of medical matters in the colonies, more especially in relation to educational facilities, it will be seen that at the commencement of our history as an independent nation, in 1776, there were between three and four thousand practitioners of medicine, supplying about three millions of people, their field of duty occupying thirteen States, embracing the whole Atlantic coast from Maine to Florida, and containing two medical colleges, two organized medical societies, and one permanent general hospital. Small as were these beginnings, they nevertheless constituted the germs from which have since developed all the educational institutions belonging to the profession in our country.

[1] See History of Medical Education and Institutions in the United States, by N. S. Davis, M.D., p. 22.

The Medical Department of the College of Philadelphia, which had been organized in 1765, with Dr. William Shippen, Jr., as Professor of Anatomy and Surgery, and Dr. John Morgan, as Professor of Medicine, had continued regular annual courses of medical instruction until 1776, when the session was broken up by the vicissitudes of war, and the most valuable movable materials of the college were privately removed to places of safety by the provost and members of the faculty. Previous to this time, Drs. Adam Kuhn and Benjamin Rush had been added to the medical faculty of the college—the first, as Professor of Materia Medica and Botany, and the second, as Professor of Chemistry. During the same time, Dr. Thomas Bond had been lecturing on clinical medicine in the Pennsylvania Hospital. On an attempt being made to resume the courses of medical instruction in the College, in 1779, political differences and suspicions caused the State Legislature to pass an act abrogating the charter of the college, removing its officers, and transferring its property to a new institution, called the "University of the State of Pennsylvania."

The new University was granted a very liberal charter and considerable endowments. The Rev. John Ewing, D.D., was appointed Provost, and an effort immediately made to organize a medical department, by offering those who had held professorships in the College, the same positions in connection with the University. Regarding the act of the Legislature abrogating the charter of the College and confiscating its property as unjust, all but Dr. William Shippen, Jr., refused the offer and continued their annual courses of instruction independently, but without legal authority to confer degrees. The Trustees of the University, finding themselves unable to fill the several medical chairs satisfactorily, agreed to confer degrees on such students as should be examined and recommended by the several professors of the College whose charter had been abrogated. By this arrangement, at the first public commencement of the University, held in Philadelphia, June 27, 1780, the degree of Bachelor of Medicine was conferred on William W. Smith and Ebenezer Crossly, and that of Doctor of Medicine on David Ramsey, who was in the service of the American Army, and at the time a prisoner in the hands of the British. These were the first medical degrees conferred by any institution created under the auspices of one of the independent States of America. This state of antagonism between the professors in the College of Philadelphia and the trustees of the University, continued until 1789, when, aided by the influence of Benjamin Franklin, after his return from Europe as foreign minister, the former succeeded in inducing the State Legislature to repeal the act of abrogation, and to restore to the College all its rights and privileges. This was done in March, 1789, but it left the University in existence, with its endowments from confiscated estates the same as before. The officers and faculty of the College of Philadelphia were immediately reinstated, with Dr. Benjamin Franklin himself as president of the Board of Trustees.

In October of the same year, Dr. John Morgan died, and Dr. Adam Kuhn resigned, leaving the chairs of Practice of Medicine, and Materia Medica and Botany, vacant. The vacancies were immediately filled, and the Medical faculty of the College as reorganized for the session of 1789–90, was composed of William Shippen, Jr., M.D., Professor of Anatomy, Surgery, and Midwifery; Benjamin Rush, M.D., Professor of the Theory and Practice of Physic; Caspar Wistar, M.D., Professor of Chemistry and of Institutes of Medicine; Samuel P. Griffiths, M.D., Pro-

fessor of Materia Medica and Pharmacy; Benjamin Smith Barton, M.D., Professor of Natural History and Botany. At the same time Dr. Shippen continued to occupy the same chair in the University of the State of Pennsylvania, and was joined in that faculty by Dr. Adam Kuhn, in the Chair of Theory and Practice of Medicine, and by Dr. James Hutchinson, in that of Chemistry.

The trustees of the College of Philadelphia not only reinstated a full corps of medical professors, but they revised their former rules in regard to medical requirements for graduation. These rules, as adopted in 1767, provided for the conferring of the degrees of Bachelor of Medicine and Doctor of Medicine. The student was permitted to apply for the first after "a sufficient apprenticeship to some reputable practitioner in Physic," attendance on "at least one course of Lectures on Anatomy, Materia Medica, Chemistry, the Theory and Practice of Physic, one course of Clinical Lectures, and attendance on the practice of the Pennsylvania Hospital one year." It was expected by the founders of the College, that those who took the Bachelor's degree would return after three years of study and practice, and take the higher degree of Doctor. Experience, however, had proved this expectation fallacious, as very few of those who entered into practice after receiving the first degree, ever returned for the second. For this reason the Bachelor's Degree was abolished, and the revised regulations adopted for the College by the trustees, November 17, 1789, and published in the Pennsylvania Gazette were as follows:—

"I. No person shall be received as a candidate for the degree of Doctor of Medicine until he has arrived at the age of twenty-one years, and has applied himself to the study of medicine in the College for at least two years. Those students, candidates, who may reside in the city of Philadelphia or within five miles thereof, must have been the pupils of some respectable practitioner for the space of three years, and those who may come from the country, and from any greater distance than five miles, must have studied with some respectable physician there, for at least two years.

II. Every candidate shall have regularly attended the Lectures of the following professors, viz.: of Anatomy and Surgery; of Chemistry and the Institutes of Medicine; of Materia Medica and Pharmacy; of the Theory and Practice of Medicine; the Botanical Lectures of the Professor of Natural History and Botany; and a course of Lectures on Natural and Experimental Philosophy.

III. Each candidate shall signify his intention of graduating to the Dean of the Medical Faculty, at least two months before the time of graduation, after which he shall be examined privately by the professors of the different branches of medicine.

If remitted to his studies, the professors shall hold themselves bound not to divulge the same; but if he is judged to be properly qualified, a medical question and a case shall be proposed to him, the answer and treatment of which he shall submit to the medical professors. If these performances are approved, the candidate shall then be admitted to a public examination before the Trustees, the Provost, Vice Provost, Professors and Students of the College; after which he shall offer to the inspection of each of the Medical Professors a Thesis, written in the Latin or English Language (at his own option) on a medical subject. This Thesis, if approved of, is to be printed at the expense of the candidate, and defended from such objections as may be made to it by the Medical Professors at a commencement to be held for the purpose of conferring degrees, on the first Wednesday in June every year.

Bachelors in Medicine who wish to be admitted to the degree of Doctor in Medicine, shall publish and defend a Thesis agreeably to the rules above mentioned.

The different Medical Lectures shall commence annually on the first Monday in November, the lectures in Natural and Experimental Philosophy about the same time, and the lectures on Botany on the first Monday in April.

BENJAMIN FRANKLIN, President of the Board of Trustees.
WILLIAM SMITH, Provost of the College and Secretary of the Board of Trustees."[1]

The Trustees of the University of the State of Pennsylvania adopted very similar regulations regarding courses of lectures and time of study for the degree of Doctor in Medicine, but they continued also to confer the degree of Bachelor, as before. One hundred and four medical students attended the Lectures in Philadelphia during the College term of 1790–1, and appear to have been nearly equally divided between the two schools. The disadvantages arising from this division of patronage were too apparent to be overlooked, and the friends of both schools soon instituted measures for an amicable union. These measures resulted in the passage of an Act of the Legislature of the State, September 30, 1791, uniting the College and the University on the terms which had been mutually agreed to by both the parties in interest. The name adopted for the united institution was the "University of Pennsylvania." Dr. John Ewing was elected Provost and Professor of Natural and Experimental Philosophy, and all the professors in the medical department of the two previous institutions were elected professors in the new one. The full medical faculty of the University, as thus constituted, was arranged as follows: William Shippen, M.D., Professor of Anatomy, Surgery, and Midwifery; Caspar Wistar, M.D., Adjunct; Adam Kuhn, M.D., Professor of Theory and Practice of Medicine; Benjamin Rush, M.D., Professor of Institutes of Medicine and of Clinical Medicine; James Hutchinson, M.D., Professor of Chemistry; Samuel P. Griffiths, M.D., Professor of Materia Medica and Pharmacy; Benjamin Smith Barton, M.D., Professor of Botany and Natural History.

The University, as thus reorganized, ceased to confer the degree of Bachelor of Medicine, and left it optional with the medical students whether they should attend the lectures on Natural History and Botany, but in all other respects adopted the "Rules respecting a medical education and the conferring of Degrees in Medicine," which have been already given as having been adopted by the Trustees of the College of Philadelphia in 1789.

We have thus sketched briefly the progress of medical instruction from its incipient beginnings in Philadelphia, to the complete establishment of the University of Pennsylvania by the formal election of the faculty above named, in January, 1792, not merely because it was the pioneer school, and one which still continues to exercise an important influence over the educational interests of our profession, but because it has served as the type or pattern for nearly all the medical schools subsequently organized in this country. While the cause of medical education was progressing, as we have detailed, in Philadelphia, the profession in New York was not idle. We have stated that, as early as 1767, a charter was granted by the Colonial government of New York for the establishment of a General Hospital in that city; that, chiefly through the efforts of Drs. Samuel Bard and Peter Middleton, a society was organized, and a hospital building nearly completed, which was destroyed by fire in 1772; and that the enterprise received liberal pecuniary aid from Sir Henry

[1] See History of the University of Pennsylvania, by Joseph Carson, M.D., pp. 95–6.

Moore, the provincial Governor, from the Legislature, from the City Corporation of New York, and from many private individuals. The loss of the building by fire, and the speedy supervention of the war for Independence, prevented all further efforts in that direction until after the close of that war. Soon after this latter event, the corporation known as the Society of the New York Hospital was revived, its work resumed, and adequate hospital buildings completed ready for occupation in 1791. The same persons who had been influential in the primary effort to establish the New York Hospital, also induced the trustees or governors of King's College, located in New York City, to establish a Medical Department of that institution, and to appoint a full medical faculty in 1768. This faculty was composed of Samuel Clossy, M.D., Professor of Anatomy; John Jones, M.D., Professor of Surgery; Peter Middleton, M.D., Professor of Physiology and Pathology; James Smith, M.D., Professor of Chemistry and Materia Medica; John V. B. Tennent, M.D., Professor of Midwifery; and Samuel Bard, M.D., Professor of Theory and Practice of Physic.

Some important differences will be noticed in comparing this faculty organization with that of the faculty just previously organized in Philadelphia. First, it makes a more complete division of labor, and at once gives a full recognition to the departments of Surgery and Midwifery, assigning to each a separate professorship on an equality with all other departments, instead of making them appendages to the more prominent departments of Anatomy and Theory and Practice of Medicine. In this respect the New York faculty was in advance, not only of that of the Philadelphia College, but also of that of the University of Edinburgh. Second, it makes no mention of the departments of Botany and of Natural and Experimental Philosophy. Third, as the number of chairs and the consequent division of labor was greater, the annual college term was made shorter by one month; the term closing in May instead of June in each year. In all other respects the regulations were very similar to those adopted by the school in Philadelphia. The first courses of lectures were given in the autumn and winter of 1768–9, at the close of which, in May, 1769, the degree of Bachelor in Medicine was conferred by the Trustees of the College on Samuel Kissam and Robert Tucker. And at the close of the succeeding college term, in May, 1770, the degree of Doctor in Medicine was conferred on one or both of the same persons. These are stated by Dr. J. B. Beck, and several other writers, to have been the first medical degrees conferred by any college in America. This is true, however, only as it relates to the degree of Doctor in Medicine. For, as a matter of fact, the College of Philadelphia conferred the degree of Bachelor in Medicine on ten students in June, 1768, but did not confer the degree of Doctor in Medicine until June, 1771.

The regular annual courses of medical instruction were continued, and attended by small classes of students, until they were interrupted by the war. During the war, the name of King's College was changed to that of Columbia College, which it still retains. Soon after the close of the war an effort was made to re-establish the medical department connected therewith. By some misfortune connected with the procuring of subjects for dissection, a violent popular outbreak, called the "Doctors' Mob," was induced, during which the dissecting-room of the college was broken up, and for three days law and order were trampled under foot. To counteract, as far as possible, the evil influences thus brought to bear upon the profession, and to improve medical science, several of the more

enterprising and younger members of the profession formed a private society, and in 1787 succeeded in inducing the magistrates of the city to establish a public free dispensary for the sick poor. Among the more prominent of those engaged in this enterprise were Drs. William Moore, Nicholas Romaine, Benjamin Kissam, Wright Post, and Valentine Seaman. They not only gave gratuitous attendance on the poor in the dispensary, but in connection therewith gave lectures on most of the branches of medicine; thereby making it the first institution connected with *practical* instruction in medicine under the corporation of the City of New York.

So great was their success that, in 1790, more than fifty students attended their instruction, and an unsuccessful attempt was made to organize an independent school under the name of the College of Physicians and Surgeons. In the autumn of 1791, the private association introduced not less than sixty students into Columbia College, and thereby induced the Legislature of the State to make a grant of $30,000 to the trustees, for the purpose of enabling them to enlarge their buildings, etc. In the following year the medical faculty was reorganized by the appointment of Drs. Bailey, Post, Rogers, Hammersly, Nicol, and Kissam, as professors, and of Dr. Samuel Bard, as Dean of the Faculty. Some of these appointments were very unsatisfactory to the students, and were followed by such a degree of opposition as to greatly interfere with the prosperity of the College, and to lead many members of the profession in the city to use their influence in favor of the establishment of another and independent medical school.

In accordance with their wishes, the regents of the University of the State of New York granted a charter for a new college in 1807, to be located in the city, and called the College of Physicians and Surgeons of New York. It was placed under the control of a board of trustees, consisting of the whole Medical Society of the city and county of New York, and the degree of Doctor of Medicine was to be conferred by the regents of the University of the State, on the recommendation of the trustees and faculty of the College. The first course of lectures was given in the winter of 1807–8, to a class of fifty-three students. In 1810 the medical department of Columbia College was finally discontinued, leaving the College of Physicians and Surgeons the only one in the State, with a class of students numbering eighty-two, and the following very able faculty, viz.: Samuel Bard, M.D., President; David Hosack, M.D., Vice President and Professor of the Theory and Practice of Medicine and of Clinical Medicine; William James Macnevin, M.D., Professor of Chemistry; Samuel L. Mitchill, M.D., Professor of Materia Medica and Botany; Valentine Mott, M.D., Professor of Surgery; John W. Francis, M.D., Professor of Obstetrics and Diseases of Women and Children; Wright Post, M.D., Professor of Anatomy.

But instead of that rapid prosperity which the friends of the institution and the regents of the University now anticipated, the very numerous board of trustees, being mostly medical practitioners in the immediate vicinity of the College, soon became distracted by opposing councils, and jealousies arose between them and the members of the faculty, which caused much difficulty and greatly retarded the prosperity of the college. These defects were corrected in subsequent years, and the institution has maintained a good reputation and leading influence down to the present time.

In 1783, the medical department of Harvard College, in Cambridge,

near Boston, was organized by the appointment of John Warren, M.D., Professor of Anatomy and Surgery; Aaron Dexter, M.D., Professor of Chemistry and Materia Medica; and Benjamin Waterhouse, M.D., Professor of the Theory and Practice of Medicine. The medical department of Dartmouth College, at Hanover, New Hampshire, was organized in 1797, chiefly through the influence of Dr. Nathan Smith, who was appointed Professor of Medicine, and for ten or twelve years taught all the branches of medicine with signal ability. The medical department of the University of Maryland, at Baltimore, was incorporated in 1807, and was supplied with an able faculty, consisting of John B. Davidge, M.D., Professor of the Principles and Practice of Surgery, and Nathaniel Potter, M.D., Professor of the Theory and Practice of Medicine, assisted by Drs. Shaw, of Maryland, and Cooke, of Virginia.

By the foregoing brief historical statements it will be seen that during the first thirty years after the close of the war for Independence, which included the first decade of the present century, seven medical schools had been organized, namely, two in Philadelphia, two in New York City, one in Boston, one in Hanover, and one in Baltimore. The two in Philadelphia had been speedily united into one, and one of those in New York had been discontinued. We find, therefore, only five medical schools in existence in the United States in 1810, with an aggregate number of medical students in attendance of about 650, of whom about 100 received in that year the degree of either Bachelor or Doctor of Medicine. Two-thirds of this whole number were in the University of Pennsylvania. Only two public general hospitals had been established, namely, the Pennsylvania Hospital in Philadelphia, and the New York Hospital in New York City.[1] The former was a very important aid to the University in attracting students to Philadelphia, by the clinical instruction which it afforded, as inaugurated by Dr. Thomas Bond soon after it was opened for the reception of patients.

All but one of these medical schools were organized as departments of colleges or universities of literature and science, already established, and all but the one began with a small number of professors, making it necessary that one man should teach two, and sometimes three, branches of medicine during each annual college term. For this reason more than any other, the medical college terms were made to commence generally on the first of October, and to continue until the following May or June. All these schools adopted, at first, the policy of conferring the degree of Bachelor of Medicine on students who had studied medicine with some reputable practitioner not less than two years, and had attended the medical instruction in the college one year, or rather one college term; and the degree of Doctor of Medicine after three years of study and two annual college terms. It must be remembered that, during the colonial period of our history, and for thirty or forty years subsequent to the achievement of our National Independence, it was the universal custom for young men who entered upon the study of medicine to become regularly apprenticed to some practitioner for a term of three or four years, during which time the preceptor was entitled to the student's ser-

[1] Since the above was written, we have learned that, in 1784, Don Andras Almonaster commenced the erection of a public or general hospital in the city of New Orleans, on the site of the one blown down in the great storm of 1779. It was called the New Charity Hospital, and cost $114,000. As Louisiana became one of the States of our Union, by purchase, in 1803, this Charity Hospital should have been included with those of Philadelphia and New York mentioned above.

vices in preparing and dispensing medicines, extracting teeth, bleeding, and other minor surgical operations, and, when more advanced in studies, in attending on the sick; and, in return, the preceptor became obligated to give the student detailed and thorough instruction in all the branches of medicine. Many of the more eminent practitioners often had several students in their offices at one time, constituting a small class who were drilled almost as regularly in their studies as they would be in a college. In some instances the term of apprenticeship was extended to six and even seven years, and was made to commence at the early age of fifteen or sixteen years. All these customs were brought by the emigrants from the parent country, and their perpetuation here was rendered more necessary by the sparseness of the population and the difficulty of access to medical schools.[1]

In the midst of such customs, and at a period in the world's history when railroads, steamboats, and other means of speedy transit were unknown, and even post-coaches were rare, it was entirely reasonable that the first idea of a medical college should be to furnish the means for a rapid review of the several branches of medical science, aided by such experiments and appliances for illustration as could be commanded, and the whole concentrated into as small a part of the year as possible. The idea of the founders of medical schools, both in Great Britain and in this country, was to make them *supplement* but *not supersede* the work of the preceptor and the medical apprentice. The study of anatomy by dissections, the illustration of chemistry by experiments, the clinical observation of disease at the bedside, were capable of being carried on in the offices of preceptors, only to a very limited extent. But by combining several preceptors, each eminently qualified in some one department, in a college faculty, with access to anatomical rooms, chemical laboratory, and hospitals for the sick, all the branches of medicine then recognized could be very well reviewed in the form of didactic instruction, in five or six months of the year. It was expressly to supply the wants here indicated, with the greatest economy of time and labor, that the medical department of the University of Edinburgh was founded in the beginning of the eighteenth century, and conferred its first degree of Doctor of Medicine in 1705. It rose rapidly to distinction among the schools of Europe, and furnished the model after which the first medical schools in this country were organized; as it was the *Alma Mater* of nearly all their first professors.

Assuming that the student would serve from two to four years of his apprenticeship to his preceptor, before resorting to a medical school, the several professors very naturally arranged their courses of instruction to begin nearly at the same time, generally in September or October, and to be completed in time for the public commencement and conferring of degrees in the following May or June. And as the Bachelor's degree was generally conferred after attendance on one full course of college instruction in the several branches taught, no gradation or consecutive order of studies could be incorporated into the college course. The addition of one or two years more of study, including a second course of college instruction, entitled the applicant to an examination for the degree of Doctor of Medicine. At the first organization of all the medical schools to which we have thus far alluded, provision was made for conferring the degrees of both Bachelor and Doctor of Medicine. But, as already men-

[1] See Contributions to the Annals of Medical Progress, etc., by J. M. Toner, M.D.

tioned, the degree of Bachelor was abandoned by the College of Philadelphia in 1789, and by the University of Pennsylvania in 1791, and by all the medical colleges in the country after 1813. The whole number of medical degrees conferred by the seven medical schools whose origin we have traced, prior to 1810, did not exceed six hundred. Very many, however, served their regular apprenticeship with the preceptor, attended one course of college instruction, and entered upon practice without a college degree; and there were not a few who entered upon the responsible duties of practice with simple certificates from their preceptors, without ever having seen the inside of a college building.

We shall not fully appreciate the relations of the medical schools to the needs of the profession at that time, unless we consider also the coincident condition of the different branches of medical science. To the active workers of the present generation, a medical college with only three or four professors, or one professor attempting to teach anatomy, surgery, and midwifery, all in one college term of five or six months, would appear hardly less than absurd. If we remember, however, that down to the commencement of the present century, the principal medical works in use were the writings of Sydenham, Boerhaave, and Cullen, the Physiology of Haller, the Anatomy of Cheselden or Monro, the Surgery of Sharp, Pott, or Jones, the Midwifery of Smellie or Hunter, and the Materia Medica of Lewis, we shall readily see that the field of medical study was limited in comparison to that which now opens before the student.

At that time, surgery had only begun to be recognized as a distinct branch from anatomy. We learn from an introductory lecture by James Spence, F.R.C.S.E., Professor in the University of Edinburgh, that "so late as 1777, when the College of Surgeons petitioned the patrons to institute a separate professorship of surgery in the University, they were opposed by Monro, then Professor of Anatomy, as interfering with his branch; and he succeeded in getting his commission altered so as to include surgery, which was thus made a mere adjunct of the anatomical course, and continued to be so taught (if it could be said to be taught) until the institution of the chair of Surgery in 1831." It was not until June 4, 1805, that Surgery was separated from the chair of Anatomy by the appointment of Dr. Philip Syng Physick as Professor of Surgery, on an equality with the other professors in the University of Pennsylvania. The department of Midwifery was still later in gaining recognition as a distinct branch of medicine. At the request of Dr. Caspar Wistar, who had succeeded to the professorship of Anatomy and Midwifery in the University on the death of Dr. Shippen, in 1808, the trustees separated the chairs, and in 1810 appointed Dr. Thomas Chalkly James the first Professor of Midwifery in that College. And yet it was not until three years later, October 11, 1813, that he was formally recognized as a member of the faculty, and attendance on his lectures rendered obligatory upon the students who applied for graduation. In New York, however, midwifery was recognized as a distinct branch at a much earlier period than in any of the other cities in which medical schools had been organized; for in the first medical faculty appointed in connection with King's College, in 1768, Dr. John V. B. Tennent was made Professor of Midwifery, apparently on an equal footing with all the other professors.

The foregoing facts are sufficient to show the limited field of medical science at the beginning of the present century, compared with the same field at the present time. If this is borne in mind, it will be seen that

the five medical schools, embracing the medical departments of the University of Pennsylvania, Harvard College, near Boston, Dartmouth College, at Hanover, the University of Maryland, at Baltimore, and the College of Physicians and Surgeons, at New York, which were either reorganized or founded *de novo* during the first thirty years of our history as an independent nation, were established on as liberal a basis, and were as well adapted to the then existing wants of the profession and the people, as any that have been organized since. As a general rule, they commenced with a small number of professors, but as the different departments of professional knowledge became better developed, and the work of instruction better systematized, there was manifested that tendency to make divisions of labor by the creation of new chairs, which has continued to the present time. In this respect the University of Pennsylvania, as the leading school, may be taken as a representative of all the rest. Commencing with only two professors, Drs. Morgan and Shippen, aided by the clinical instruction of Dr. Bond in the Hospital, in 1765, the number was increased by the addition of the chairs of Chemistry and Materia Medica, in 1768–9; and on the merging of the College of Philadelphia with the University of the State of Pennsylvania, in 1791–2, the number of chairs was increased to six, by the addition of professorships of Institutes of Medicine, and of Botany and Natural History. A further addition took place by the creation of a separate chair of Surgery, in 1805, and one of Midwifery, in 1810. From the year just named the number of medical schools began to increase with great rapidity.

A medical department was established in connection with Yale College, in New Haven, in 1810, but the first course of instruction was not commenced until 1813. In 1812, the Regents of the University of the State of New York incorporated the College of Physicians and Surgeons of the Western District, located in Fairfield, Herkimer County. The Vermont Academy of Medicine, located at Castleton, Vermont, received a charter from the Legislature of that State in 1818. The same year, a medical school was organized as a department of Transylvania University, at Lexington, Kentucky, chiefly through the influence of Drs. Dudley, Richardson, and Blythe. In January, 1819, the Legislature of Ohio passed an act incorporating the Medical College of Ohio, in Cincinnati. In 1820, the Medical School of Maine was organized as a department of Bowdoin College, at Brunswick, Maine, with a faculty consisting of Drs. Nathan Smith, John D. Wells, and Parker Cleaveland. In 1821, a medical school was organized in connection with Brown University, at Providence, Rhode Island, but was soon after discontinued. The medical school of the University of Vermont was established in Burlington, in 1822. A school called the Berkshire Medical Institute, was organized in Pittsfield, Massachusetts, under the charter of Williams College, in 1823. The Medical College of South Carolina was established in Charleston, in 1824, and supplied with a full corps of professors, including the well-known names of Drs. Ramsey, Holbrook, Dickson, Prioleau, Frost, Ravenal, and Elliot. The Medical Department of Columbian College, in the District of Columbia, was organized in 1825, chiefly through the influence of Drs. Thomas Sewall and Frederick May, of Washington.

In the winter of 1825, the Legislature of the State of Pennsylvania passed an act under which a new medical school was organized in Philadelphia, in connection with a literary institution called Jefferson College, at Canonsburg; and hence the new medical school took the name of Jefferson Medical College, and, in its progress since, has attained a prosper-

ity and influence equal to that of the best medical colleges in this country. The Medical Department of the University of Virginia, located at Charlottesville, in that State, was organized in 1825, and has continued to the present time, teaching the different branches of medicine in the same manner as the various branches of science are taught in other departments of the institution. The medical school of the Valley of Virginia was established at Winchester, Virginia, in 1826, on nearly the same plan as the Medical Department of the University, at Charlottesville. It attracted but a small number of students, and appears to have been discontinued several years since. In 1827, the Washington Medical College was organized in Baltimore, on the same plan as the majority of American medical colleges. The Medical College of Georgia, located at Augusta, was incorporated by an act of the Legislature of that State in 1830, and the first course of instruction was given in 1832–3. The Willoughby University, in Ohio, was chartered in 1834, and its first course of instruction commenced in the autumn of 1835. The Medical Department of the University of Louisiana, at New Orleans; the Medical Institution of Geneva College, at Geneva, New York; the Medical Department of Cincinnati College, Cincinnati, Ohio; and the Vermont Medical School, at Woodstock, Vermont, were chartered by the Legislatures of the respective States in which they were located in the year 1835.

The Medical Department of the University of Louisville, Kentucky, was organized in 1837, and the Medical Department of the University of the City of New York, the same year. The Medical Department of Hampden Sidney College, at Richmond, Virginia, was organized in 1838. The Albany Medical College, at Albany, New York, and the Medical Department of Pennsylvania College, at Philadelphia, in 1839. The Missouri Medical College, at St. Louis, Missouri, was organized in 1840, and the St. Louis Medical College, in the same city, in 1841. The Legislature of Illinois granted a charter for the Rush Medical College, in Chicago, in 1837, but a faculty was not organized for instruction until 1843. The Cleveland Medical College was organized at Cleveland, Ohio, in 1843. The Medical Department of the University of Buffalo was organized in Buffalo, New York, in 1846. The Starling Medical College and Hospital was organized at Columbus, Ohio, in 1847. The Medical Department of the University of Michigan, at Ann Arbor, was instituted in 1849. The Medical Department of the University of Nashville, at Nashville, Tennessee; the College of Physicians and Surgeons, at Keokuk, Iowa; and the Woman's Medical College of Pennsylvania, at Philadelphia, were organized in 1850.

The Medical College of Virginia, at Richmond; the Medical Department of Georgetown University, at Washington; and the Cincinnati College of Medicine and Surgery, at Cincinnati, were created in 1851. The Savannah Medical College, at Savannah, Georgia, and the Miami Medical College, at Cincinnati, were established in 1852. The Atlanta Medical College was commenced at Atlanta, Georgia, in 1855. The Medical College of the Pacific, at San Francisco, was organized in 1858. The Chicago Medical College, Medical Department of the Northwestern University, was organized in 1859. The Medical College of Mobile, Alabama, and the Long Island College Hospital, in Brooklyn, New York, were organized in 1860. The Bellevue Hospital Medical College was established in the city of New York in 1861. The Woman's Medical College of the New York Infirmary, located in the city of New York, was created in 1864. The Medical Department of Willamette University,

located at Salem, Oregon, was commenced in 1866. The Medical Department of Howard University was organized in 1867. The Medical Department of the University of South Carolina, at Columbia, and the Detroit Medical College, at Detroit, Michigan, were commenced in 1868. The Medical Department of the University of Wooster, at Cleveland, Ohio; the Kansas City College of Physicians and Surgeons, at Kansas City, Missouri; the Louisville Medical College, at Louisville, Kentucky; the Medical Department of the Iowa State University, at Iowa City; and the Medical Department of the Indiana University, at Indianapolis, all had their beginning in 1869.

The Woman's Hospital Medical College, at Chicago, and the Medical Department of Lincoln University, at Oxford, Pennsylvania, were organized in 1870. The Free Medical College for Women was organized in the city of New York in 1871. The Medical College of Evansville, Indiana, was chartered in 1846, and reorganized in 1872. The College of Physicians and Surgeons of Syracuse University, at Syracuse, New York, and the College of Physicians and Surgeons at Wilmington, North Carolina, were incorporated in 1872. The Medical Department of the University of California, at San Francisco, was first organized under the name of the Toland Medical College in 1864, and became a department of the University in 1873. The Medical College of the University of the State of Missouri, at Columbia, Missouri, and the Texas Medical College and Hospital, at Galveston, Texas, were organized in 1873. Medical schools have recently been established in Portland, Maine, and in Baltimore, Maryland, the exact dates of the formations of which are not at hand.

From the foregoing statistics we learn that, during the thirty years intervening between the close of the war for Independence and 1810, seven medical schools were organized; in the thirty years intervening between 1810 and 1840, twenty-six new medical colleges were added to the list; in the thirty-five years since 1840, the number of new medical schools created is forty-seven; making the whole number of medical educational institutions established in the United States, during the first century of our history as a nation, eighty. We have not included in these numbers five or six mere abortive attempts to form medical schools in different localities, but which were so transient as to leave a record difficult to trace. Of the eighty which have been established, seventeen have been discontinued or suspended, leaving, at this date, sixty-three medical colleges now in active operation in this country. Of these, Maine has two, New Hampshire one, Vermont three, Massachusetts one, Connecticut one, New York nine, Pennsylvania three, Maryland three, Virginia two, South Carolina one, Georgia three, Alabama one, Louisiana two, Texas one, Tennessee one, Kentucky three, Missouri three, California two, Oregon one, Iowa two, Illinois three, Indiana three, Ohio seven, Michigan two, and the District of Columbia three, leaving thirteen States without any medical college now in operation. Four of the schools included in the foregoing list, namely, two in New York City, one in Philadelphia, and one in Chicago, are established for the exclusive education of women in medicine. The whole number of students attending the medical colleges in 1810 was about 650, of whom about 100 graduated at the close of the college terms for that year. The population of the United States at that time was 7,239,881. In 1840, the whole number of students in the colleges was about 2500, of whom about 800 received the degree of Doctor of Medicine. The population of the United States

in that year was 17,069,453. During the college terms for 1875–6, the whole number of medical students in attendance on the colleges was 6650, of whom 2200 received the degree of Doctor of Medicine. The population of the States at this time is over 40,000,000. Without claiming absolute accuracy for the foregoing figures, they are sufficiently close for all the purposes of comparison. And they show clearly, notwithstanding all that has been said about the rapid multiplication of medical schools, and the increased numbers of students and graduates, that the colleges and the students, during the last thirty-five years, have increased in a ratio only about equal to the increase of the population of the country. The whole number of those engaged in teaching as professors in the several medical colleges, at this time, is about five hundred.[1]

As has been already stated, the origin of medical schools in this country was solely from individual efforts, put forth from time to time, as the ambition of the individuals or the supposed wants of the country demanded, and not from any well-digested scheme or official plan of professional education adopted either by the States or by the General Government. The same remark is true, not only of their origin, but also of their continuance and multiplication to the present time. Whenever and wherever the Legislature of any one of our States has been asked to grant a charter for a medical college, as a rule the request has been complied with. And in the few instances in which such requests have been denied, the parties interested have seldom found difficulty in forming a connection with some literary college or university, already having authority to grant degrees in medicine, as well as in general science. Some of the State Legislatures, in addition to liberally granting charters for medical colleges, have also occasionally appropriated a few thousand dollars to aid in the erection of suitable buildings, but rarely, if ever, to endow professorships, or to defray any of the current expenses of such institutions. In the State University of Michigan, and possibly in one or two other State Universities, the medical professorships, like those of the other departments, are sustained by the income from the general endowment, independent of the fees derived from the medical students. We may say, in general terms, therefore, that the whole system of medical education in this country, represented to-day by sixty-three medical colleges distributed among twenty-four different States, sustained by the active work of over five hundred professors, and annually aiding in the education of nearly seven thousand students, is the spontaneous outgrowth of the profession itself, self-reliant, and almost wholly self-sustained. Originating among a free people, under the *ægis* of various educationally independent States, apparently striving to keep pace in the increase of their number and efficiency with a population which, in one short century, has increased from three millions to forty millions, and extended over a territory from the Atlantic to the Pacific, and from the great interior Lakes to the Gulf, under circumstances of the freest competition, these schools constitute a subject worthy of the most careful study.

To what extent have these schools been adapted to the real wants of the profession and people of these States? Wherein have they failed to keep themselves adjusted to these needs or wants, as the country has

[1] In the above statistics we have not included colleges or schools for teaching exclusively dentistry or pharmacy, or exclusive dogmas in medicine. Of the first there are eleven; of the second, thirteen; of the third there are three, called Eclectic, and eight or nine, Homœopathic.

advanced to the present time? If failures in adjustment have taken place, in what do they consist, and how can they be remedied? Let me ask a continuance of your patient attention, while I answer as briefly and directly as possible these most important questions, and my task will be done.

We have already seen that our medical colleges had their origin at a time when medical science and art occupied a far narrower field than at present. A time when obstetrics was yet mostly in the hands of unlettered midwives; surgery an appendage to anatomy; organic chemistry, histology, and even physiology, as now recognized, hardly known. A time, too, when it was the universal practice for regular students of medicine to apprentice themselves to private preceptors of reputation, from whom they expected to receive the greater part of their professional education. The great and pressing need, at that time, was for schools in which, after gaining a knowledge of the text-books, the rude pharmacy of his preceptor's office, and the individual experience of the preceptor himself, during two or three of the first years of his study, the student could review the whole in connection with such experimental demonstrations as could be given only in the laboratory, the dissecting room, and the clinical wards of the public hospital. It was to supplement, not supersede, the work of the private preceptor.

Precisely this was what the medical schools were adjusted to do, and they fulfilled the object well. Hence, although originating in different States, wholly independent of each other, and in direct rivalry for patronage on which they depended for support, they were remarkably similar in their organization and requirements. At first, the number of professors was small, and the college term eight or nine months, offering the Bachelor's Decree after three years' study, and one college term, and the Doctor's Degree after one or two more years, and a second course of college attendance. But as most of the students lived in small towns and country districts remote from the colleges, making attendance on the lectures both tedious and expensive, only a part of those engaging in the study of medicine ever reached a medical college, and most of these, after taking the Bachelor's Degree, never returned to take a second course and the higher degree of Doctor. These circumstances constituted a strong inducement for the colleges to concentrate the annual period of instruction into as short a time as possible, both for the purpose of increasing the number of students who could afford the means of attending, and the number who would take the second degree. Under these influences, the first thirty years sufficed to cause the Bachelor's Decree to be abandoned by all the schools, the number of professors in each to be doubled, and the length of the annual college term to be shortened one-third. And in twenty-five years more, from the same causes, aided efficiently by the fact that the degree conferred by the colleges became practically recognized everywhere as a sufficient *license* to practise medicine in all its departments, the colleges, with but one exception worth noting, had each from five to seven professorships occupied by as many different professors, and an annual college term of only from twelve to sixteen weeks, during which the students, in one class, listened to from five to six lectures daily, on as many different topics, besides attending to dissections and clinical instruction when such were accessible.

The requirements for the Doctor's Degree were, three years study with some regular practitioner of medicine, including attendance upon two such courses of college instruction, the one being chiefly a repetition of

the other; the writing of a thesis on some medical subject; the possession of a good moral character; the attainment of twenty-one years of age; and the sustaining of a creditable examination in the several branches of medicine at the close of the second course of lectures. It will be seen that, in these requirements, there was no reference to any standard of preliminary education to be attained by the student before entering upon his professional studies, except the ability to write a thesis. The requirement of a knowledge of the ancient languages, and the writing of a thesis in the Latin language, were abandoned on the full reorganization of the University of Pennsylvania, in 1792. The relinquishment of natural philosophy, natural history, and botany, as requirements, soon followed, leaving only the single indirect trace of any non-professional education, to which we have alluded. Under these conditions and tendencies, by the end of the second thirty years of our history, the number of medical colleges had increased from five to forty-one; the number of students attending them from six hundred and fifty to twenty-five hundred, and the ratio of those graduating, each year, from less than one in six, to one in three.

Here we see a system of medical colleges originating spontaneously to supply the wants of a free and rapidly increasing people, and open to the most free and unrestrained rivalry, actively developing two apparently opposite results. In one direction, the schools justly vie with each other in increasing the number of their professors in full consonance with the rapid advancement of medical sciences; they sagaciously seek out and enlist the services, as teachers, of the most learned, eloquent, and industrious men to be found in the profession; they spend time and money freely in filling laboratories, anatomical rooms, and museums with all the means for efficient teaching and illustration. So far their free rivalry has reference only to their office as teaching bodies—institutions for imparting instruction—and is productive only of the highest good to the profession and the people. But the anomaly consists in the fact that, at the same time, the same institutions have been rapidly shortening their annual courses; cutting off all collateral requirements; failing to grade the branches of medical study, as they have increased in number and extent, so as to adapt them to the several years of pupilage; and even reducing the final examinations to the simple process of asking a few oral questions in the mysterious "green room." This most unfortunate tendency of our experiment in permitting the freest rivalry in the establishment of medical schools, results directly and necessarily from the fact that the degrees they confer, and the diplomas they give, have been permitted throughout the whole country, with only a few temporary exceptions, to have all the force and effect of a license to practise medicine. It requires but a moderate familiarity with the motives that govern human actions, to see clearly that in a country where there are no entailments of estates, and where the great body of young men who seek the profession are without pecuniary fortune, and largely dependent on their own industry for the means of education, as well as reputation and fortune in after life, the question "where can I get the degree of doctor, which is equivalent to a license to practice, and a full admission into the ranks of the medical profession in the shortest time, and consequently with the least expenditure of time and money?" exerts a very great, if not controlling influence, in determining where the student shall attend his college instruction.

Not that medical students are a whit less conscientious, in their desire

to fully qualify themselves for the responsible duties of our profession, than those who seek any other calling in life. But present necessity, or even convenience, easily controls when there comes with it the flattering thought that, at another time, after having earned a little money by practice, all deficiencies can be supplied by a season of reviewing in a school of the largest facilities. Just on this half-unconscious delusion, hundreds are induced to go where the requirements in time and money are least, regardless of all other advantages. The medical college in a country village, remote from all facilities for clinical instruction in hospital or dispensary, and but scantily supplied with subjects for dissection, can issue to its graduates just as large a diploma, couched in just as unintelligible Latin, and having much the same influence with the people, as the school in a metropolitan city, where its students can have the largest facilities for clinical and practical study. Hence it is not strange that, before the end of the seventh decade of the past century of our existence as a nation, about forty medical colleges had been organized, only sixteen of which were so located as to afford their students any proper facilities for clinical instruction; and that these sixteen were attended by little more than one-third of the whole number of those who attended medical colleges.

The general acceptance of the college diploma as full admission into the profession, thereby uniting in the hands of the same men the business of teaching and the power of licensing, has continued to the present day; and is wholly responsible for the fact that, while we have sixty-three medical colleges to-day, one third of them are so located that they can afford their students no advantages for clinical instruction worthy of mention; and all, except three or four, still attempt to crowd instruction in all the departments of medicine upon the attention of mixed or ungraded classes, in annual college terms of from sixteen to twenty weeks, and exact only two such strictly repetitional courses for graduation. This state of things, in regard to our medical schools, is made still worse by the fact that, during the century under consideration, the system of private medical pupilage has undergone a complete change. At the beginning of that period, as we have already seen, the private study, under a master, was a protracted and serious work, and the resort to the college was simply to review and more fully illustrate that work. But steadily, as medical colleges increased in number, as populations became more dense, and as steamboats and railroads increased a thousand fold the facilities for travel, the work of private pupilage relaxed. Indentures of medical students, as pupils to the more noted practitioners, long since ceased, and the relations of student and preceptor have become merely nominal in practice, in nine cases out of ten consisting in little more than the registry of the student's name in the doctor's office, permission to read the books of his library or not as he chooses, and the giving of a certificate of time of study for the student to take to the medical college where he expects to graduate.

The relative position of the private pupilage and the collegiate studies has undergone a complete practical reversal. The latter, instead of reviewing and supplementing the former, has become the student's chief reliance for the acquisition of medical knowledge; and hence, to have maintained its adaptation or adjustment to the needs of the profession, should have not only increased the number of its professors and its means for communicating knowledge, but also the length of its annual courses, and the division or gradation of its classes in accordance with their period of study, and in proportion to the greatly enlarged field of medical know-

ledge to be acquired. And such would have been, to-day, the grand result worked out by our experiment of self-originating, self-sustaining, and unrestricted competition in the establishment and maintenance of medical schools, had they been restricted to their only appropriate function as institutions for imparting medical instruction and advancing medical science, instead of being hampered and perverted from their natural course by assuming the office of licensing institutions. And could this incubus be removed to-day, another quarter of a century would not pass before every medical college in our country would have its annual course of instruction extended to six months; its curriculum and classes so graded that the attention of each student should be restricted to such branches as are adapted to his period of advancement in study; and nine-tenths of all our medical students would be in attendance on those colleges only that could afford proper facilities for full clinical and demonstrative instruction.

Let the only question presented to the mind of the student, when choosing the college he shall attend, be where can he most certainly obtain that amount and variety of medical knowledge which will enable him successfully to pass the examination of an independent board of examiners, acting under liberal and enlightened rules and modes of testing the student's knowledge, and we shall have nothing to fear either from the number, or the rivalry, of our medical schools. The injurious tendencies of our system of uniting the work of teaching and that of licensing to practise, in an unlimited number of independent medical colleges, was seen at an early period, and clearly pointed out; and by none more clearly and forcibly than by some of those engaged in the colleges themselves.

So true is this that the Legislatures of some of the States, in organizing and regulating their respective State Medical Societies, made some ineffectual attempts to lessen the evil by legislation. This was particularly true in South Carolina, Maryland, Delaware, Massachusetts, and New York. As early as 1839, at an annual meeting of the Medical Society of the State of New York, the following resolution was reported by a committee, and, after free discussion in the Society, was adopted by a vote of fourteen to four: "Resolved, That the right of teaching ought to be separated as much as possible from the power of conferring degrees or licenses." The following year a committee, consisting of Drs. James R. Manly, of New York City, T. Romeyn Beck, of Albany, and John McCall, of Utica, submitted to the same Society an able and interesting report on the whole subject of medical education, in which occurs the following cautious but significant language: "But in view of the diploma becoming depreciated by the rapid establishment of new schools, it may well become a question deserving serious consideration, whether at no distant period the rights of teaching and licensing should not be *disjoined*. An incidental difficulty to the adoption of this suggestion, is the fact that we are surrounded by institutions in other States, which might or might not follow it, and thus our students be induced to desert our own colleges."[1]

In 1837, the same view was advocated by some of the ablest members of the profession in Philadelphia, and they proceeded so far as to organize an institution for the purpose of examining candidates and of conferring degrees, wholly independent of the business of teaching. A petition

[1] See Transactions of the New York State Medical Society for 1840.

signed by one hundred and twenty-six physicians, residents of that city, was presented to the Legislature of the State, asking for a charter giving legal effect to their organization, but the charter was not granted and the project failed.

In 1844, the subject was again brought prominently under discussion in the meeting of the New York State Medical Society, by him who now addresses you. The discussion of the same subject was continued in the annual meeting of 1845, and resulted in the call issued by that society for a convention of delegates from all the medical colleges and societies in the United States, which was held in New York, in May, 1846, and from which originated the American Medical Association. I make these historical allusions to show that neither those engaged in medical teaching nor the profession at large have been unmindful of the evil to which I have attached so much importance. Yet it still exists in all its force. That the colleges have failed to keep themselves adjusted to the needs of the profession in regard to the length of their annual courses of instruction, the systematic classification of the branches included in their curriculums, the corresponding grading or division of their classes, and the exaction of a reasonable standard of preliminary education, has been still more fully appreciated and acknowledged.

Not only is this appreciation indicated by the criticisms in our medical periodicals and the discussions in our medical societies, and by the more general efforts of the colleges, since 1850, to increase the number of their professors, and the fulness of their curriculums, by piecing out their annual courses of instruction with two or three weeks of preliminary lectures at the beginning, and short spring courses at the end of the regular terms—all of which the student might attend or not as he chose—but in a still more formal manner by the proceedings of two or three conventions of delegates from the various schools, in which all the defects here stated relating to preliminary education, inadequate length of the annual courses of instruction, and the urgent need of a systematic division of the branches taught into groups appropriate for each year of study, and the consequent grading of the classes, with annual examinations of each class, have been fully stated, and a thorough plan of remedying them devised and urgently recommended to the schools for their adoption.

The first of the conventions to which I allude was held in Cincinnati, in May, 1867, and was presided over by the learned Prof. Stillé, of the medical faculty of the University in whose buildings we are assembled to-day. The second was held in the city of Washington, in May, 1870, and was presided over by the justly distinguished head of the faculty of the Jefferson Medical College of this city. A third convention of less formal character was held in this city, in June of the present year. If you ask me why these reasonable and highly important recommendations have not been adopted by the greater part of the schools, I can only point you for answer to the paragraph already quoted from the report on medical education made to the New York State Medical Society, in 1840, by that learned trio composed of Beck, Manly, and McCall. Or, more directly, to the fact that while the faculty of each school frankly acknowledges the defects in adaptation to the present enlarged field of medical science and art, and the urgent needs of the profession, each waits for the other to move first, lest, by placing higher requirements upon the time and resources of the student, it should cause its own halls to be deserted for those of its less exacting neighbor.

The efforts in this direction, however, have not been entirely fruitless

of practical results. In 1859, the Chicago Medical College, now the Medical Department of the Northwestern University, was organized for the express purpose of testing the practicability of establishing a school with a thoroughly graded and consecutive system of instruction. Its curriculum was made to embrace thirteen professorships, arranged in three groups, one appropriate for each of the three years of study required. The students attending were correspondingly divided into three classes, junior, middle, and senior. Each class was required to devote its time thoroughly to the group of branches and lectures belonging to its year of advancement in study, and to be examined fully in those branches at the end of the college term. Each of the three courses was continued six months of the year, and actual attendance on hospital clinical instruction, and practical work in the chemical, anatomical, and microscopic, or histological laboratories, was added to the requisites for eligibility to graduation. The very satisfactory success of this institution during the past fifteen years, and its present prosperity, certainly demonstrate the practicability of the scheme.

In 1871, the medical school of Harvard University, one of the oldest and most influential medical institutions in our country, also adopted a fully graded system of instruction, dividing her classes, and extending her courses of instruction throughout the collegiate year, and has continued this plan to the present time, adding annually to the perfection of its details, and adding also to her own prosperity and influence. The new medical school of Syracuse University, New York, has practically adopted the same scheme; and the annual announcements of several other medical schools, for the present year, including some of the most influential and important institutions in the country, give unmistakable evidence of their having taken initial steps in the direction of this most desirable change.

But our medical schools, aided by the work of the private preceptor, do not constitute the whole educational force or influence operating upon the profession in this country. Our social or society organizations, City, County, District, State, and National, have exerted, throughout the whole period of our history, a most potent influence over the educational interests of the profession. We had intended to sketch briefly the history of the more important of these organizations, but must not trespass further upon your time and patience on this occasion. It is sufficient to say that these society organizations, by their annual reunions of the profession in almost every State and important city in our wide domain; by the opportunities they afford for the presentation of papers, and comparison of views in free discussion, not only in relation to scientific and clinical matters, but in relation to every interest whether of medical science or medical polity, have exerted indirectly an influence over the progress, the education, and the general character of the profession, hardly second to that of the organized schools. And if the profession, as represented in these social organizations, would boldly move on in the exercise of its own most important right and duty—by fixing for itself both the standard of preliminary and professional education necessary for young men to attain before admittance into its ranks, and by appointing the necessary tribunals for enforcing that standard, thereby leaving the colleges to their only legitimate work, that of imparting instruction—the latter would speedily adjust themselves perfectly to the actual educational needs of the profession.

Because we have endeavored, in reviewing the progress of our educa-

tional institutions during the past century, to indicate what we regard as their most important defects, let no one infer that we belong to that class, who, in any degree, undervalue the past work or present influence of our medical schools. We do not agree with those who would compel every young man who desires to spend his life in alleviating the sufferings of the sparse populations of our mountains and prairies, to spend the best part of his youth in the vain endeavor to become an adept in the native languages of Cicero and Hippocrates; nor would we discourage the laudable ambition of that large and most valuable class of our young men, who are largely dependent on the proceeds of their own labor for their education, as well as for their advancement in after life, nor foster the indolence of the more wealthy by copying the five, six, or seven years of professional collegiate study from the institutions of Europe. Neither do we agree with those who regard the establishment of a National professional school by our general government, or the endowment of State colleges, with professors salaried out of public funds, as the panacea for our ills. To invoke the patronage of either National or State Governments, in this country, in the regulation and support of medical schools, is simply equivalent to asking that the lobbies of every legislative body in the country shall be annually filled with the log-rolling satellites of every "pathy" and "ism" of the day, that the professorships of our colleges shall be transformed into political sinecures, and that the colleges themselves shall become the foot-balls of partisan politicians.

On the contrary, we believe that our system of medical college instruction, with all its defects, has developed in strict consonance with the spirit of a free and enlightened people, in the comparatively short period of one hundred years, a body of medical men as enlightened, enterprising, industrious, and self-sacrificing, as faithful to the interests of the people, and animated by as noble an *esprit de corps*, as is to be found in any country on the globe. And not only so, but that these same schools have done their full share in creating and sustaining that progress in medical science and literature, which has been demonstrated to this Congress so fully in the most intersting Addresses to which we have listened, on the various departments of medical science and art.

Let us, then, in the same self-reliant, independent spirit, which actuated those who founded, and with the same untiring zeal and generous emulation which characterized the host of others who have sustained and developed, the medical institutions of our country thus far, endeavor to manage wisely the high trust they have left us. Let us neither be blinded by reverence for the past, nor be fretful with impatience because clearly perceived evils will not flee at our bidding, nor yet, with childish weakness, call on the Hercules of government to do our work for us; but let us with boldness yet persevering steadiness of purpose, carry forward our educational organizations, both collegiate and social, enlarging their foundations, improving their adjustments, and adding to their superstructure; and we shall thereby most certainly enable those who come after us in celebrating the next centennial anniversary of our national progress, to review our work with the same pleasure and profit that we derive to-day, in contemplating the works and characters of those whose names are an honor to the century which has just passed.

ADDRESS ON THE MEDICAL STAFF OF THE UNITED STATES ARMY, AND ITS SCIENTIFIC WORK.

BY

J. J. WOODWARD, M.D.,

SURGEON, UNITED STATES ARMY.

GENTLEMEN: The Centennial Medical Commission having requested the Surgeon General of the Army to depute an officer of the Medical Staff to occupy an evening during the session of the International Medical Congress by giving some account of the scientific work of the Medical Department of the Army, the Surgeon General has designated me as the officer to undertake the task, and, in obedience to his commands, I am here to-night to comply with the invitation of the Commission.

In the discharge of this duty, I wish first of all to explain, as briefly as possible, how it happens that a certain class of scientific work, intimately connected in its nature and results with the progress of practical medicine and surgery, is undertaken by the Medical Bureau, and I hope to make it clear to you that the kind of work to which I refer is of national importance, and that it can be better and more economically done by the Medical Bureau of the Army than in any other way. I shall, then, endeavor to lay before you in a sketchy way, for a single evening will not suffice to go into any branch of my subject in detail, the character of the work already done, and of that actually in progress, with some hints as to matters which might profitably be undertaken in the future, did the means placed at our disposal permit.

It is the duty of the Surgeon General to provide for the maintenance of the health of the Army, as well as for the humane treatment of its sick and wounded. The first duty is, if possible, more important and more delicate than the second, and both are rendered much more difficult to discharge efficiently than might be anticipated in view of the small number of men in our little army, by the comparatively great number of separate military posts, and by the vast extent of the territory over which they are scattered.

The total strength of the Army, officers and men, is, after all, less than twenty-eight thousand, hardly the strength of an army corps of the army of the great German Empire, but it is broken up into little detachments, so that there are nearly two hundred permanent garrisoned posts, and almost half as many more detached parties, of variable strength, requiring medical care. I think it quite safe to affirm that the actual strength of the army might be increased tenfold without materially increasing the labor of its medical administration, provided the number of posts and detachments remained the same as now.

These posts and detachments are scattered over all parts of our wide territory. They are most numerous in the great interior wilderness, remote from the comforts and facilities of more settled communities. Many of them on the southern coast and the Mexican frontier are exposed to frequent visits of epidemic yellow fever, the scourge of our southern

seaboard, which, as late as 1867, destroyed in a single season nearly one per cent. of the whole strength of the army of that year. Moreover, the troops stationed on the Indian frontier are most of the time exposed to all the hardships and privations of a state of actual war. I know that a great statesman has recently declared that Indian conflicts are not war, and that it has been decided that gallantry in these bloody struggles shall no longer receive the poor reward of brevet rank; but the bullet wounds that are received are none the less dangerous because they are inflicted by a savage foe, and the privations and hardships of campaigns in the wilderness against a well-armed enemy who greatly out-numbers our little force, have precisely the same tendency to produce disease and death that the same conditions would exert could they exist in a war against a civilized foe. In a recent disaster, which is only too fresh in the memory of my hearers, about one per cent. of the whole strength of the army, among them two medical officers,[1] perished in a single day. Let us hope that such a catastrophe may never occur again; but similar incidents, though the total loss in each case was less, have happened before, and almost every year since the close of the civil war has had its share of victims fallen in obscure but bloody conflicts.

Now, it is self-evident that the officer charged with the medical and surgical care of any army must keep himself informed as to its sanitary condition; as to the number and character of the cases of disease actually occurring, and the circumstances under which they are developed; as to the number and character of the wounds, and the circumstances under which they are sustained. This information would be indispensable to the intelligent action of the Surgeon General of the Army, even were he charged with no other duties than the assignment of the medical officers and the purchase and distribution of the medical supplies required for the treatment of the sick and wounded; it is still more necessary if he is expected to supervise the sanitary condition of the army with a view to the suppression, as far as possible, of all preventable diseases. In the army of every civilized nation in modern times, therefore, the medical officers actually serving with troops are required to keep a record of the cases of sickness and wounds under their care, and to report them at stated intervals to a central bureau. It is, furthermore, self-evident, that if these reports are at all numerous or voluminous, as they must be, either if the army is large, or if it is scattered in numerous detachments, the Surgeon General will be physically unable to perform the task of personally examining them with any thoroughness, and must assign this duty to others, distributing it among a sufficient number of competent assistants, who must analyze the reports received, and bring to the attention of the Surgeon General such facts and deductions as require his official action. In other words, the Surgeon General of an army, to act efficiently, requires a personal staff of medical officers who enjoy his confidence, and who must be competent to analyze thoroughly the various reports assigned to them, and, if necessary, to advise intelligently on any matters as to which their opinions may be required by their chief.

In our own army, the system of reports established for the purposes just indicated is briefly as follows:—

The medical officer of each post or station is required to keep a register of the sick and wounded under his care, in which each patient is entered

[1] Assistant Surgeon George E. Lord, United States Army, and Acting Assistant Surgeon James M. De Wolf.

by name, with the date at which he is taken on sick report; the diagnosis of his disease or injury, and the termination of the case, being subsequently entered in appropriate columns. From this register a monthly report of sick and wounded is prepared, and forwarded to the Surgeon General from each post or station. It contains a statistical statement of the number of cases of each kind of disease or injury under treatment at the commencement of the month, the number taken on sick report during the month, and the number of each recovered, died, discharged the service, or otherwise disposed of, and the number remaining under treatment at the close of the month. The report also includes a list of the deaths and discharges from the service on surgeon's certificate of disability, giving in each case the name of the soldier and the cause of death or discharge, and has a place reserved for any necessary explanatory remarks.

These reports, consolidated and analyzed at the Surgeon General's Office, keep the Surgeon General constantly informed as to the health of each individual post, of each military department, and of the whole army; acquainting him with the actual amount of sickness, its nature, mortality, and relationship to strength, with the number of wounds and injuries, their character, mortality, and the localities at which they have occurred. The deaths and discharges for disability are recorded in alphabetical registers for convenient reference, and subsequently serve to give necessary information to the accounting officers of the Government, and especially to the Commissioner of Pensions, in case discharged soldiers, or the heirs of the deceased, make application for pensions or other allowances due under the laws of the land. The medical officer of each post or station is required, besides, to make special reports of interesting cases, giving the full histories of such as appear to him of sufficient importance, and in case of the outbreak of epidemic diseases, giving monthly, besides the usual statistical report, a list of all the soldiers attacked, with the date of attack and the date of recovery or death. In such epidemic outbreaks the medical officer is required to investigate the cause of the outbreak, to ascertain, if possible, the mode of introduction, if the disease is introduced from without, and to record the circumstances under which it has originated if it appears to have resulted from local causes. These investigations serve as the basis of a special report, which is required of the medical officer in charge of any post or detachment in which an epidemic outbreak may occur.

As intimately connected with the question of the causes of disease, the medical officer in charge of each post is required to keep a meteorological register, a transcript of which must be furnished to the Surgeon General at the close of each month. Moreover, at the close of each year the medical officer of each post is required to make to the Surgeon General a general sanitary report on the health of the post, with remarks on the diseases which may have prevailed, and suggestions, if any occur to him, as to the improvements or changes which in his opinion may be advantageously introduced, with the view of improving the health of the garrison.

Injuries, wounds, and surgical operations are made the subject of separate special reports, giving the names of the soldiers, and the particulars of each case.

Medical officers examining recruits are obliged to record the name and physical description of each recruit examined, and in the case of

rejected recruits, the cause of rejection. A transcript of this record is furnished to the Surgeon General at the close of each month.

Now, I think, it will be understood without argument, that such a mass of reports as I have just indicated, embracing annually the observations and experience of several hundred well-educated medical men, stationed at as many different places, must contain a great deal of information which, besides its administrative value, must have no little significance in connection with the interests of progress in scientific medicine and surgery. I wish, on the one hand, to insist that all these reports are indispensable from the mere administrative point of view. Without them, and especially, I may add, without their intelligent analysis, the Surgeon General of the Army, whatever his personal ability, would be but a figure-head, powerless for any efficient interference in behalf of the health of the army. On the other hand, I wish also to insist on the fact, that by a very small additional expenditure of labor, clerical force, and money, beyond what would be indispensable for the intelligent administrative use of the facts collected, they can be made to subserve a much wider purpose, and the usefulness of the work, which is indispensable to the army itself, for the sake of which primarily it is done, can be vastly extended so as to benefit the medical profession at large, and, through the medical profession, the sick and injured in every walk of life.

These considerations would afford a sufficient motive for much of the scientific work that has been done by the Medical Bureau in the past, and for much that is still in progress; but there are other circumstances to be considered of equal, indeed, as I think, of even greater significance.

A few years ago our country was convulsed by a great civil war which lasted for four long years. During this time about a million of men were constantly under arms in defence of the national flag; about two hundred thousand of them died of disease, about one hundred thousand of wounds. The Confederate armies, though somewhat smaller, were numerous enough to resist effectively till the very close of the struggle. Their losses can hardly have been much less than those of the national armies. After the close of the war the national armaments were disbanded; the great general hospitals, several hundred of which were in operation, were closed as rapidly as the patients under treatment could be provided for, and it became necessary, for administrative reasons, to order that as each was closed its books and records should be sent to the Surgeon General's Office in Washington. In that office there had also accumulated during the war a vast quantity of reports of sick and wounded, and other records which had been required for administrative purposes during the war. The records thus accumulated embraced over sixteen thousand folio volumes of manuscript record books, and, I suppose, several tons of manuscript reports and papers. Urgent administrative reasons demanded that these records should be examined, classified for convenient reference, and, to a certain extent, that their contents should be analyzed. The pension laws of the United States are so framed that it became necessary, in almost every one of the hundreds of thousands of applications for pensions, to apply to the Surgeon General for the hospital history of the soldier concerned. Subsequently, liberal laws were adopted granting artificial limbs and other prothetic apparatus to those who had lost limbs or been otherwise mutilated, and trusses to those who had been ruptured during the war. This bounty was to be dispensed under the direction of the Surgeon General, and again the records of his office came into requisition, both to protect the

Government against fraudulent claims and to secure the rights of honest applicants. For all these strictly administrative purposes a vast amount of clerical work became necessary, and that this work might effect its end, it was absolutely necessary that it should be directed at every step by competent medical officers.

Now, it became evident from the very first, that by the expenditure of a comparatively small amount of additional labor in the supervision of this work, by a comparatively small increase of the clerical force, and other expenditures absolutely required for mere administrative reasons, results might be attained the publication of which would be beneficial to mankind, and it seemed as though it would have been indeed a great national crime to have lost this opportunity to utilize, in the service of humanity, the experience which it had cost so much blood and so many tears to acquire.

The work of analyzing these records for the double purpose just indicated was entrusted to the very same medical officers who have charge of the current work of the bureau to which I referred a little while ago. Even if no intention of publication had been entertained, these officers would have required for the efficient discharge of their duties, supposing them to have been limited to mere administrative ends, the use of a good consulting library; and if they had simply preserved for subsequent comparison the pathological specimens with which special medical and surgical reports were frequently accompanied, and without which these reports would often be only partially intelligible, an Army Medical Museum would have gradually been built up, however slow the process might have been.

At the time the war broke out nothing deserving the name of a Medical Library existed in Washington; and the incipient medical libraries in other cities, even at such great medical centres as Philadelphia, New York, and Boston, were exceedingly deficient in the very class of books which were most frequently needed for consultation. Indeed, these medical libraries, built up by the voluntary contributions of a generous profession which numbers but few wealthy men in its ranks, were deficient in every direction, and, had the best of them been situated in Washington, it would but imperfectly have satisfied the necessities of the case. There was, therefore, no hope of supplying the want unless the Surgeon General's Office should be able to accumulate a library of its own. In like manner, the correct interpretation of many of the pathological specimens received implied the ability to compare them with others, such as ought to be found in a General Pathological Museum. But no considerable pathological museum existed in America. Small museums had indeed been created by the industry and liberality of the professors of several of the medical schools in the great northern cities, but these had been founded with special reference to the needs of the elementary instruction of medical students, and contained no wealth of accumulated material such as is often needed for purposes of comparison in arriving at the intelligent interpretation of an individual case. Such museums had been built up in the older civilized countries of Europe for the most part by Government aid, and without Government aid it was and still is impossible that any considerable collection of the sort should ever grow up in America. It was evident, therefore, that if the officers on duty in the Surgeon General's Office were to enjoy the advantages of consulting such a collection, it must be created by the office itself. Now, here again, it was clear from the first that by a small addi-

tional expenditure beyond what would have been necessary to create such a library and museum as would be thoroughly efficient for the merely practical purposes of the Medical Bureau, a National Medical Library and a General Pathological Museum might be created, which would meet a want long felt by every medical man in America who has ventured into the domain of original research.

The considerations hitherto presented are, let me hope, sufficient to make it plain that it was the bounden duty of the Surgeon General's Office to undertake that scientific work of which enough has already been published to enable the medical profession throughout the world to form a judgment as to its character, and as to the fitness of the medical officers to whom it has been intrusted to accomplish the task which they have undertaken. The medical criticism of the old world has already proclaimed its verdict as to both points in an outspoken manner, and I will not be deterred by any false modesty, on behalf of my colleagues or myself, from making the statement that the verdict has been altogether favorable. As for the medical profession of our own country, my fellow-citizens—so many of whom I see around me to-day—how shall I find words to express my feelings? Your generous sympathy and encouragement have sustained us from the very first. Many of you served with us during the war, and aided in accumulating those vast stores of experience which we are now endeavoring to utilize. We were so fortunate as to secure your co-operation at the beginning, and your support has never failed us yet; I believe it never will, if we continue to deserve it. It is largely owing to your influence that the National Legislature has been induced to supply us with the funds, without which our work could not have been carried on; and however scanty these funds have appeared to some of us, when compared with the sums devoted by other civilized governments to similar purposes, we have never forgotten how liberal the appropriations have been when compared with any ever made before by our own National Government for any medical purpose. Not merely have you constantly strengthened our hands, and supported us in our endeavors to accomplish our work, but, ever since the close of the war, you have labored with the National Legislature to secure for the officers of the medical staff a reasonable share of rank and pay, and these efforts were at last, during the recent session of Congress, successful in securing legislation which, if it did not do for us all you had hoped, at least placed us on a better footing than we had ever hitherto enjoyed. It is, therefore, altogether an appropriate thing that I should explain, as I am now doing in your presence, the character of the work we are endeavoring to perform.

I have now to present to you, as briefly as possible, some details with regard to the nature and extent of the scientific work of which I have been speaking; but first, let me remark that the observations and reports which form the basis of this work are due to the intelligence and industry of the whole medical staff. This fact must never be lost sight of in estimating the character and importance of the work. It represents no mere individual observations and opinions, but the conjoined and systematic labor of a considerable body of trained and trustworthy medical men. The officers entrusted with the labor of digesting these observations, and preparing them for the press, have constantly endeavored, in all their publications, to give full credit to their brother officers at the various military posts, whose original labors are the foundation of all the scientific work that has been done, and of all that can be done at the Surgeon General's Office. I refer you confidently to any of our publications in

illustration of this statement. This work of the officers of the Medical Staff deserves the appreciative recognition of all who are interested in the progress of Medical Science. Not merely have they made with alacrity the observations and reports required of them in the discharge of their military duties, but their voluntary labors have been meritorious and important. Those of you who practise medicine in cities, and enjoy all the stimulus of converse with intelligent fellow-laborers and of competition for success, can hardly realize the difficulties under which most of the work of these medical officers is done, at remote and usually isolated stations, or amidst the hardships and perils of campaigns in the wilderness against the Indians, with no special stimulus to investigation except the love of science and desire for usefulness.

Next, I have to remind you that the work of analyzing these observaions, comparing them with each other and with similar observations in other lands, preparing the results of these studies for publication, and seeing them through the press, has been from the beginning to the present time, with the exception of two or three publications, to which I will refer specifically hereafter, performed by but three medical officers; and it may be of interest to those who love to see economy in administration above all other things, for me to state that these three officers have received as remuneration for their labors during the last ten years nothing more than the modest emoluments belonging to the rank of Assistant Surgeons in the Army. One of them was, it is true, promoted to the grade of Surgeon a few months ago, but this was simply the accidental consequence of his place on the Army Register; the others remain as before. The three officers to whom I refer are my colleagues, Drs. Billings and Otis, and myself.

Now, it would not be just to these officers if I did not state that they have never been, and are not now, free to devote their whole time to the scientific work entrusted to their care—each is also charged with certain administrative duties which demand a portion of his time and attention.

Thus, my colleague, Dr. Billings, besides the charge of the Library and various special duties connected especially with the sanitary condition of barracks and hospitals, has always had to do a good deal of administrative work in connection especially with the purveying of medical supplies and the accountability of medical officers for supplies issued to them.

My colleague, Dr. Otis, besides his duties as Curator of the Army Medical Museum, as the officer in charge of its Surgical, Anatomical, and Miscellaneous sections, and as the officer entrusted with the preparation of the Surgical History of the Civil War, has had administrative work to do in the way of furnishing information from the Surgical records with regard to the numerous applications for artificial limbs and prothetic apparatus, and other current work connected with the Division of Surgical Records.

For myself, besides the charge of the Medical, Comparative Anatomy, and Microscopical sections of the Museum, the Chemical Laboratory of the Surgeon General's Office, and the preparation of the Medical History of the Civil War, I have had charge, since its organization, of the Record and Pension Division of the Surgeon General's Office, a purely administrative bureau, which for several years employed about one hundred clerks, and which still has thrust upon it ample work to employ the same number, although parsimony in legislation has reduced the force to less than half, so that the work is rapidly falling behindhand. Some notion

of the responsibility attaching to this bureau can be formed when I state that, since 1865, the hospital histories of about three hundred thousand deceased or disabled soldiers have been traced through the record books and furnished to accounting officers of the Government, especially to the Commissioner of Pensions, and the insufficiency of the clerical force now authorized, will be appreciated, when I state that between twelve and thirteen thousand such applications are lying unanswered on the table of my chief clerk as I speak these words.

Now, you will readily understand that the administrative duties to which I refer must not merely increase the responsibilities, but must necessarily occupy a portion of the time of the officers concerned, with the inevitable effect of diminishing the amount of scientific work which it is possible for them to perform. Yet my experience in the office has convinced me that it would not be wise to relieve these officers of this administrative responsibility and throw it upon a different set of officers. The same records are to be used both for administrative and scientific purposes, and the double work can best be performed under the same heads. The most economical, and at the same time the most efficient means of diminishing the burdens of these officers, and of increasing both the quantity and the value of the scientific work which it is possible for them to perform, would be to provide them with a really adequate clerical force, and with a sufficient number of competent assistants. I do not speak to-night in any complaining spirit, but it would be worse than useless to pretend that adequate clerical and other assistance has ever been supplied to us. This is a naked fact, which it is my duty to make known, and which you must constantly bear in mind in appreciating the amount of work which we have as yet published. That under the circumstances we should have been able to do as much as we have—that since the close of the war we should have been able to prepare for publication the various works with which you are acquainted—the publications of the Surgeon General's Office, edited by us and already issued, constituting over six thousand quarto pages[1]—could only have been achieved by tireless industry and a genuine devotion to our task.

Coming next to the details of this scientific work, I may remark that a portion of the reports received at the Surgeon General's Office which are susceptible of scientific treatment, refer to the conditions under which the soldier lives. Here belong the meteorological reports and a large portion of the annual sanitary reports.

Prior to the civil war, the meteorological observations made by the medical officers of the army were published from time to time by the Surgeon General's Office, the greater portion having been edited by the lamented Coolidge. All students of the Climatology of the United States are familiar with these works, which long furnished the only reliable information with regard to the climate of our western territories, and, indeed, contain information with regard to many districts which is still the only information printed.

During the civil war the fierce necessities of the struggle caused the suspension of these observations, but they were resumed after its close, and, at the present time, observations of the temperature three times a day, the rain-fall, appearance of sky, and direction and force of the winds, are recorded under the direction of the medical officer of every permanent military post, and barometrical, and other special observations, at

[1] See Appendix.

selected posts. Since the Signal Service has been conducting its extensive meteorological observations in the more settled portions of the country, however, it has been thought by the Surgeon General that the interests of science, as well as of economy, would be best subserved if he should discontinue the publication of the meteorological observations made by the medical officers of the army, and accordingly an arrangement has been made by which the monthly means and other portions of the meteorological reports needed for reference in the Surgeon General's Office are briefed in convenient books, and the original reports are then turned over to the Signal Office, for use in conjunction with the observations made under the supervision of that bureau.

The annual sanitary reports received from the several military posts, since the close of the war, have served as the basis for the preparation by my colleague, Dr. Billings, of two bulky volumes, which contain descriptions of the several military posts, their barracks and hospitals, embracing a good deal of new information with regard to the medical topography of many parts of our country, especially the western territories, and also containing abstracts, prepared under my own supervision, of the sickness and mortality, and of the meteorological conditions, of the various posts for several years.

Another portion of the reports contains information with regard to the physical characteristics of the men who become soldiers; I refer to the monthly reports of the officers entrusted with the physical examination of recruits. These reports contain the name, nativity, former occupation, age, social condition, height, weight, chest measurement, complexion, and color of eyes and hair of each recruit examined, and in the case of rejected recruits, the nature of the disability on account of which enlistment is refused. These reports, if subjected to scientific treatment at stated intervals, say every five or ten years, would give valuable hints as to the improvement, deterioration, or stability of the physical characteristics of our population. I know that a very great number of these recruits are of foreign birth, but, as this is carefully specified in each case recorded, there would be no difficulty in the way of the separate analysis of the facts with regard to the native born, and the total number of observations which have accumulated since the war is large enough to be of considerable importance. The two splendid volumes recently published by Colonel J. H. Baxter, U. S. A., recently Chief Medical Officer of the Provost Marshal General's Bureau, and now Chief Medical Purveyor of the Army, contain an analysis of a vast number of similar facts observed by the examining surgeons in the course of the several drafts made during the civil war. I am clearly of the opinion that the analysis of the subsequent observations would possess sufficient scientific value to warrant the comparatively small amount of labor and expense requisite to do the work and publish it; but I regret to say that the office has not yet been able to secure enough clerical aid to assign the necessary force to this work, and nothing has as yet been done in this direction. I must hope that it may be possible in the near future to undertake the analysis of the reports received during the last ten years.

Still another portion of the reports received contains information with regard to the diseases and injuries from which our soldiers suffer while in actual service. Here belong the monthly reports of sick and wounded, the special reports of cases, the reports relating to epidemic diseases, and the various reports of wounds and surgical operations.

The monthly reports of sick and wounded are analyzed and consoli-

dated by districts as soon after their reception as possible, and constantly furnish information as to the actual condition of the health of the army. From the statistical tables produced by their consolidation the brief statements made by the Surgeon General in his annual reports are prepared. They have also furnished the data for the abstracts published in the volumes prepared by Dr. Billings, mentioned a few moments ago.

With these exceptions, these valuable statistical tables remain unpublished. I am decidedly of the opinion that they contain a great deal of information much too useful to be lost. Indeed, I think, if the Surgeon General's Office could obtain the necessary force of clerks and assistants to make an annual publication of these reports, accompanied by the accounts of interesting medical and surgical cases received during each year, it would be an important contribution to medical science; but with the means at our disposal, and the other demands made upon us, this has been hitherto quite out of our power. The special reports upon epidemics have, however, been utilized to some extent in the publication of two works prepared by myself, on the Epidemic Cholera and Yellow Fever in the Army during the years 1866 and 1867, and my colleague, Dr. Otis, has prepared a large volume, published in 1871, containing a report of 732 surgical cases treated in the Army from the close of the war to the date of publication. Thus the material in question has at least been partially utilized, but I think that the portion which as yet remains unpublished fully equals in value, and certainly exceeds in quantity, that which has thus far been printed. In connection with the subject of epidemic diseases, just alluded to, I ought also here to mention the investigation of the Epidemic Cholera which in 1873 afflicted the civil population of the United States. By an act of Congress the Surgeon General was directed to detail a medical officer of the army for this investigation, and Assistant Surgeon (now Surgeon) Ely McClellan, U. S. Army, was designated for this purpose. This officer made an elaborate report, which was published as a Congressional document. With it was printed a bibliography of cholera, prepared at the Surgeon General's Office by Dr. Billings, which is, I believe, the most complete list of the works on this subject that has yet appeared.

Perhaps it would be most convenient, in this connection, to say a few words with regard to the Chemical Laboratory of the Surgeon General's Office. The creation of this Laboratory was one of the necessities of the civil war. Immense purchases of medical supplies were being made, and it very frequently happened that efforts of the most ingenious kind were employed to defraud the Government. Moreover, among the great number of medical officers in service, there were many who were inexperienced, and some who were ignorant, and complaints were often made as to the quality of the medical supplies issued which were not justified by the facts. Under these circumstances it was constantly necessary that the Surgeon General should have the opinion of a chemical expert on whose advice he could rely, and it was this that led to the organization of the Chemical Laboratory. Soon other bureaus, especially the Subsistence department, began to apply to the Surgeon General for advice in the matter of supplies purchased or about to be purchased, and it is safe to affirm that the Laboratory of the Surgeon General's Office was the means of saving hundreds of thousands of dollars to the Government. The Laboratory was established on the most economical basis, its personnel never having exceeded two individuals, a chemist and an assistant, both employed as acting assistant surgeons. Their time has been almost

exclusively occupied in the examination of supplies about to be purchased for the army, or of supplies already purchased, with regard to which complaints had been made. If this Laboratory could be more liberally provided for, it might have a much wider field of usefulness. Scientific questions of a chemical character constantly arise in connection with the medical service of the Army, which might then profitably be investigated.

I have next to present a few remarks with regard to the Medical and Surgical History of the late Civil War. The project of such a work was conceived early during the struggle, suggested, no doubt, by the volumes published by the British Government on the Medical and Surgical History of the War in the Crimea. As early as June 9, 1862, the intention to prepare such a work was announced to the Medical Staff by a circular from the Surgeon General's Office, and all medical officers were requested to co-operate in the undertaking by collecting details of cases, and other material for the work. The supervision of the work of collecting surgical material was assigned, by the same circular, to Dr. J. H. Brinton, at that time Surgeon U. S. Volunteers; that of collecting medical material was assigned to me. Dr. Brinton was relieved from this duty in October, 1864, and his place supplied by my present colleague, Assistant Surgeon Otis, U. S. Army, then Surgeon U. S. Volunteers, who, for the three years previous, had served continuously in the field as Surgeon of the 27th Mass. Regiment of Infantry. Both my colleagues and myself did our best to collect material for the work in view, and our efforts were constantly sustained and encouraged by the Surgeon General.

In November, 1865, the Surgeon General issued a document, now well known as Circular No. 6, which was accompanied by two somewhat detailed reports, prepared by Dr. Otis and myself, "On the extent and nature of the materials available for the preparation of a Medical and Surgical History of the Rebellion." The object of this circular was to acquaint the medical profession with the character of the materials collected, and to secure, if possible, favorable public opinion in behalf of the legislation necessary to provide means for preparing the work and completing its publication. This merely preliminary document was widely circulated, and effected the end for which it was designed, Congress, in July, 1866, making an appropriation for the preparation of plates and illustrations for "A first part of the Medical and Surgical History of the Rebellion;" but it was not until March 3, 1869, that Congress at length authorized the actual printing of five thousand copies of the first part of the work.

Meanwhile, anxious that the information collected on some of the more important surgical points should be made public, the Surgeon General published, in 1867 and 1869, two important monographs prepared by Dr. Otis; the first on Amputations at the Hip-joint, the second on Excisions of the head of the Femur for shot injury.

The labor of preparing the first part of the Medical and Surgical History for publication had now so far advanced that it went to press soon after the necessary authority was obtained, and in December, 1872, the first part of the Medical and Surgical History was issued from the Government Printing Office. This part consisted of a medical volume, a surgical volume, and an appendix, the whole occupying 1800 pages quarto. The Medical volume, edited by myself, was devoted to the medical statistics of the war. Some necessary explanatory remarks were offered in the introduction to this volume, but detailed comments on the

statistics were reserved for the second part of the work. The appendix consisted of the reports of the Medical Directors of armies and departments, and of other medical officers, which were believed to be of historical value. The Surgical volume, edited by Dr. Otis, contained a chronological summary of losses in battles and engagements, and a detailed discussion of the statistics and reports relating to special wounds and injuries of the head, face, neck, spine, and chest.

It was not until June, 1872, that legislation was obtained for continuing the publication of the work. Congress then passed an act for its completion and publication, in two parts, of eighteen hundred pages each, in addition to the parts already published.

In accordance with this legislation the publication of the second part of the work was commenced, and the Surgical volume of my colleague, treating of special wounds and injuries of the abdomen, the pelvis, the back, and the upper extremities, has, as you know, been brought successfully to its completion, and was issued from the Government Printing Office during the present summer. This volume contains 1024 pages quarto. I had hoped that its companion Medical volume, which will embrace a discussion of the symptoms, pathology, and treatment of those diseases which were the chief causes of the sickness and mortality among our soldiers during the war, would have appeared simultaneously. In this hope I was doomed to disappointment. In the winter of 1873 and 1874 my health unexpectedly gave way, and for several months I was incapacitated for any literary work. For a long time subsequently, I was obliged in accordance with the counsel of my medical advisers, to limit my hours of labor to a minimum, so that, with all my other duties, I made during the two years which followed my first illness but little progress on the Medical History. I am thankful to say, however, that my health appears at length fully restored, and I trust, when my labors in connection with the Centennial come to a close, that I will be able to resume the printing of the volume and to bring it to a conclusion in a reasonable time.

The third part of the History is expected to consist, like the others, of two volumes. The Surgical volume will treat of the wounds and injuries of the lower extremities; of luxations and fractures from other causes than gunshot; of burns, scalds, and frost-bites; of generalities on gunshot wounds, amputations, etc.; of the use of anæsthetics; of the materia chirurgica, and of the transportation of the wounded. The Medical volume will treat of the hospital system inaugurated during the war, the system of medical supplies, and other kindred matters.

Before passing to another topic, I desire to say a word with regard to the work of my colleague, Dr. Otis, on the Surgical History. How painstaking and accurate it has been, how laboriously he has collected the former experience of other lands to throw light on our own, and to aid in its interpretation, is well known to all of you who have looked into his volumes. But I wish to remind you, in connection with the statements I have made, as to the time required for the preparation of this work, of the extent of the data to be handled as compared with those of any former war. The previous surgical histories of wars, published under government auspices, were that prepared by Dr. T. P. Matthew, on the Surgery of the English Army in the Crimean War, and those of M. Chenu on the Surgery of the French Army in the Crimea, and during the Italian War. Dr. Matthew had to deal with 12,166 surgical cases; Chenu with 40,586 for the Crimean, and 19,590 for the Italian war.

The reporter for the American war had to deal with the reports of over 270,000 cases of wounds. Moreover, my colleague undertook a task comparatively new in military surgery, which certainly appears to me of the greatest importance. In the British and French reports, when a wounded man was invalided or pensioned his history was terminated. Dr. Otis attempted to trace all the more important cases down to the date of publication, and this the organization of the Pension Bureau enabled him to do successfully in the majority of instances. At the time this plan was determined upon, it was believed to be altogether new. It is now known, however, that Professor Hannover, of Copenhagen, had conceived a similar plan, and applied it in the case of the invalids of the war of 1864.

Similar investigations have since been made by Lœffler, Mossakowsky, and Berthold, though in connection with a much smaller number of cases than occupied my colleague.

I cannot dwell longer to-night on the Medical and Surgical History of the War of the Rebellion. I pass to a few remarks concerning the Library of the Surgeon General's Office. I have already indicated the reasons for the commencement of this Library. The first appropriation of money for the purpose was made by Congress not long after the close of the war. For two or three years ten thousand dollars, subsequently, however, only five thousand, were appropriated annually. This has been expended with great economy and discretion, under the supervision of my colleague, Dr. Billings. A great many books have also been acquired by exchange, or have been presented to the library. As a result, this library now contains about 40,500 bound volumes and 41,000 pamphlets. Although, for obvious reasons, under the charge of the Surgeon General, this library is essentially the Medical Section of the Library of Congress. For several years the Librarian of Congress has not purchased medical books, leaving that branch of the subject to the Surgeon General's Office. In 1874, the Government Printing Office issued a small edition of a Catalogue of Authors, prepared by Dr. Billings, which formed three quarto volumes of about 2000 pages, similar in style to the Catalogue of the Congressional Library. This Catalogue is in the possession of every public medical library in the country, and is very useful, as far as it goes, to students who desire to avail themselves of the resources of the library in connection with medical researches of any kind. The library itself is thrown open to all medical men who choose to use it.

Although far from complete, this library is now one of the great medical libraries of the world; and right here I wish to say, that even double the money expended upon it would not have made it as valuable as it now is but for the generous assistance of the profession of this country. Many of our physicians have ransacked their own libraries to supply us with works which, in many instances, we could not otherwise have obtained, especially the older American books and journals. The extent to which this has been done is the best proof of the general desire of the medical profession of the United States that this library should speedily become a complete library of reference on medical subjects.

I know that a few individuals have objected that Washington is not the best place for a great medical library, and seem to think it a pity that it cannot be established in Philadelphia or New York, where the number of physicians is so much larger; but the usefulness of such a library is not to be measured by the number of casual readers, but by the number of original investigators who consult it in connection with their own work.

It is only through the work of these men that a great library becomes generally useful to the whole profession. These original investigators are comparatively few in any city, but almost every city has some of them. Wherever the National Medical Library might be, the majority of the medical investigators of the country would have to travel to consult it. Until very lately, such men had to travel to Europe for the same purpose. It is important that this should no longer be necessary. It is important that there should be in at least one place in our country a complete medical library, and this we will make at the Surgeon General's Office, if we can get the means. There is no probability that such a library will ever be built up in the United States except by Government aid. This is also what has happened in all other countries. If we could secure for the purposes of the library exclusively an annual appropriation of ten thousand dollars, we could in a very few years make this library the most complete in the world.

One point further I desire to mention. To give the library already collected the highest degree of usefulness, a subject catalogue is now imperatively demanded. Dr. Billings has undertaken such a work. With dauntless industry he has not merely arranged the cards representing the separate treatises in the library according to their subjects, but he has undertaken to make separate cards for all the original essays contained in all the medical periodicals in the library. About 275,000 such cards have already been prepared. He now desires to obtain the authority to have the Government Printing Office publish a Subject Catalogue prepared from these cards. A specimen fasciculus of this catalogue has already been issued, and most of you who are specially interested in medical bibliography have already seen it. Dr. Billings estimates that the catalogue, if completed on the plan of this fasciculus, would make about five volumes of a thousand pages each. He is abundantly willing to undertake the labor if Congress can be induced to authorize the printing of the work. An appeal will be made to Congress on this subject at its next session, and if the medical profession of the country agree with me, that the publication of such a catalogue would be a work useful to every medical investigator in the land, I feel sure that by an expression of their views they can secure the success of the undertaking.

Lastly, I have to say a few words with regard to the Army Medical Museum. I have already indicated the circumstances under which it originated. It has now acquired very considerable extent, containing very nearly 19,000 specimens. The specimens collected during the civil war were almost all illustrations of military surgery and of camp diseases. But, since the war, it has begun to acquire a broader scope, and we now aim to make it a National Medical Museum. The collection now embraces, besides the Medical and Surgical sections, a Microscopical section, sections of Human and Comparative Anatomy, and a Miscellaneous section.

The section of Comparative Anatomy is yet in its infancy, and almost all the specimens have been collected by medical officers of the army, so that it has cost altogether but a few hundred dollars. There are about 1500 skeletons and crania, almost all of American vertebrates, in this section. A check list of them, prepared by Dr. H. C. Yarrow, has recently been published in pamphlet form. Those interested in this special subject can obtain copies of it at the Hospital of the Medical Department of the Army at the Centennial grounds.

The section of Human Anatomy is chiefly remarkable for its collection

of human crania, which now number about 1600. These chiefly represent the native American races, including the prehistoric mound-builders, and the various modern tribes, from the Esquimaux at the North to the Patagonians at the southern extremity of South America. The careful measurement of these crania, under the supervision of Dr. Otis, constitutes a genuine addition to the science of ethnology. An abstract of these measurements has been prepared by him, and recently published in pamphlet form. Ethnologists can obtain copies at our hospital on the Centennial grounds, or of the Surgeon General.

Catalogues of the Medical, Surgical, and Microscopical sections were published in 1867. That of the Surgical section was prepared by Assistant Surgeon A. A. Woodhull; that of the Medical section by myself; and that of the Microscopical section by Assistant Surgeon E. Curtis. Since these catalogues were published the collections have doubled in size. The publication of a catalogue of the additional specimens, or a revised catalogue of the whole, would be a useful work.

It gives me pleasure to state that the interest taken in this collection by the medical profession of the country is being annually more and more frequently displayed by the presentation of valuable medical and surgical specimens from all parts of the country. Such specimens are always acceptable, and especially, I may remark, that those which have served as the basis of original communications published in the medical journals have especial interest. You can all appreciate how useful it would be; how many misunderstandings would have been prevented if the actual specimens which have served for certain pathological descriptions could have been somewhere preserved and accessible to the criticism of subsequent investigation. But no medical museum that is not national in its character will ever serve as the central point for such a collection.

The actual appropriations of money for our Museum have never exceeded five thousand dollars a year. The sum is not a liberal one, and much more could be advantageously expended if it could be obtained.

The Centennial Medical Commission, in giving the invitation to which I have responded to-night, expressed the wish that I would endeavor to represent to your eyes in some way the character of some portion of our collection. In compliance with their request, I have naturally selected my illustrations from the Medical and Microscopical sections, which are under my own immediate direction. I have made use of photography for the purpose, and Mr. Edgerton, of J. W. Queen & Co., 924 Chestnut street, has kindly undertaken to exhibit the pictures on the screen. First, I exhibit a series of photographs, novel, I think, in character, representing certain pathological conditions of the intestinal canal.

[Twenty-five lantern slides, representing pathological alterations of the intestinal mucous membrane, were here exhibited, and briefly commented on.]

My other illustrations are taken from the Microscopical section. This section was originally established for the purpose of preserving the specimens acquired in the study of the pathological anatomy of some of the diseases of soldiers. Sections of morbid growths, and other specimens sent to the Surgeon General's Office by the medical officers of the Army for an opinion as to their nature, have been added, with a certain number of other specimens, especially in the direction of normal and pathological histology. The collection now contains about 7000 permanently mounted microscopical slides. A single assistant, paid as a clerk of the first class,

constitutes, under my direction, the whole personnel available for the work.

The process by which the photographs I am about to exhibit were prepared, was, as most of you are aware, brought to its present state of perfection by my own original investigations. A complete misconception exists in certain quarters as to the time I am able to devote to work of this class. It has been simply my amusement—my relaxation from the daily routine and toil of the other labors which I have outlined to you to-night. For years all the work of this kind I have been able to accomplish has been done on Sundays and holidays.

A part of this work was undertaken for the sake of the Medical History of the War.

[Twelve photo-micrographs were here shown, exhibiting perpendicular sections of diseased intestines, the magnifying power with which the slides were taken ranging from 50 to 200 diameters. This was multiplied by 50 by the lantern projection.]

Another portion represents incidental histological work.

[Here fifteen micro-photographs were shown, including nine of blood-corpuscles, to demonstrate the impossibility of discriminating between the blood of man and certain other mammals. These slides were taken with 150 to 1000 diameters.]

Still another portion represents work undertaken in connection with the investigation of attempts to defraud the Government.

[Here fourteen slides, each magnified 150 diameters, were exhibited, illustrating an investigation into the so-called "calf-hair goods," undertaken at the request of the Honorable Secretary of the Treasury.]

In connection with these investigations, the question of the scientific certainty of microscopical appearances has constantly been thrust upon me, and I have been forced to the conclusion that not unfrequently, especially when high powers are used, the false appearances resulting from diffraction and interference have been mistaken for real structure. This would be a melancholy conclusion, were I unable to point out how such misinterpretations may be avoided. It is impossible to do this in detail on such an occasion as this, but I will show you a few pictures in illustration of my meaning.[1]

[The address was concluded by the exhibition of a series of slides representing the real and spurious appearances of certain diatoms often employed by microscopists as test objects, the slides being magnified from 500 to 2500 diameters, and this increased by the lantern fifty times.]

APPENDIX.

Publications of the Surgeon General's Office.

[1863–1876.]

Circular No. 9. War Department, Surgeon General's Office, July 1, 1863. Consolidated Statement of Gunshot Wounds. By Surgeon J. H. Brinton, U. S. Volunteers, 11 pp. 8vo.

Circular No. 15. War Department, Surgeon General's Office, Washington, September 8, 1863. Sickness and Mortality of the Army during the first year of the War. By J. J. Woodward, Assistant Surgeon, U. S. Army, pp. 8, 8vo., with 6 diagrams.

[1] [The descriptions of the several slides would require for their clear understanding the reproduction of the pictures referred to, and are therefore, at the request of the author, omitted.—Editor.]

Circular No. 6. War Department, Surgeon General's Office, Washington, March 10, 1864. Reflex Paralysis. By Acting Assistant Surgeons S. Weir Mitchell, George R. Morehouse, and W. W. Keen, Jr., pp. 17, 16mo.

Circular No. 1. War Department, Surgeon General's Office, Washington, June 10, 1868. Report on Epidemic Cholera and Yellow Fever in the Army of the United States during the Year 1867. By Brevet Lieutenant Colonel J. J. Woodward, Assistant Surgeon, U. S. Army, pp. 156, 4to.

Circular No. 2. War Department, Surgeon General's Office, Washington, January 2, 1869. A Report on Excisions of the Head of the Femur for Gunshot Injury. By Brevet Lieutenant Colonel G. A. Otis, Assistant Surgeon, U. S. Army, pp. 141, 4to.

Circular No. 3. War Department, Surgeon General's Office, Washington, August 17, 1871. A Report on Surgical Cases treated in the Army of the United States from 1865 to 1871. By Brevet Lieutenant Colonel G. A. Otis, Assistant Surgeon, U. S. Army, pp. 296, 4to.

Circular No. 4. War Department, Surgeon General's Office, Washington, December 5, 1870. Report on Barracks and Hospitals, with Descriptions of Military Posts. By Brevet Lieutenant Colonel J. S. Billings, Assistant Surgeon, U. S. Army, pp. 494, 4to.

Circular No. 5. War Department, Surgeon General's Office, Washington, May 4, 1867. Report on Epidemic Cholera in the Army of the United States during the Year 1866. By Brevet Lieutenant Colonel J. J. Woodward, Assistant Surgeon, U. S. Army, pp. xviii., 65, 4to.

Circular No. 6. War Department, Surgeon General's Office, Washington, November 1, 1865. Reports on the Extent and Nature of the Materials available for the preparation of a Medical and Surgical History of the Rebellion. Medical Report by Brevet Major J. J. Woodward, Assistant Surgeon, U. S. Army; Surgical Report by Brevet Lieutenant Colonel G. A. Otis, Surgeon, U. S. Volunteers, pp. 166, 4to.

Circular No. 7. War Department, Surgeon General's Office, Washington, July 1, 1867. A Report on Amputations at the Hip-joint in Military Surgery. By Brevet Lieutenant Colonel G. A. Otis, Assistant Surgeon, U. S. Army, pp. 87, 4to.

Circular No. 8. War Department, Surgeon General's Office, Washington, May 1, 1875. A Report on the Hygiene of the United States Army, with descriptions of Military Posts. By Brevet Lieutenant Colonel J. S. Billings, Assistant Surgeon, U. S. Army, pp. lix., 567, 4to.

Catalogue of the Surgical Section of the United States Army Medical Museum. Prepared, under the direction of the Surgeon General, by Brevet Major A. A. Woodhull, Assistant Surgeon, U. S. Army. Washington: Government Printing Office, 1866, pp. 664, 4to.

Catalogue of the Medical Section of the United States Army Medical Museum. Prepared, under the direction of the Surgeon General, by Brevet Lieutenant Colonel J. J. Woodward, Assistant Surgeon, U. S. Army. Washington: Government Printing Office, 1867, pp. 136, 4to.

Catalogue of the Microscopical Section of the United States Army Medical Museum. Prepared, under the direction of the Surgeon General, by Brevet Major E. Curtis, Assistant Surgeon, U. S. Army. Washington: Government Printing Office, 1867, pp. 161, 4to.

[For Catalogues of the section of Human and Comparative Anatomy, see Centennial pamphlets *infra*.]

Catalogue of the Library of the Surgeon General's Office. By Brevet Lieutenant Colonel J. S. Billings, Assistant Surgeon, U. S. Army. Washington: Government Printing Office, 1872, pp. 454, 4to.

Catalogue of the Library of the Surgeon General's Office. By Brevet Lieutenant Colonel J. S. Billings, Assistant Surgeon, U. S. Army. Vol. 1, A—L, pp. 1193, 4to. Vol. 2, M—Z, pp. 956, 4to. Supplement, pp. 319, 4to. Washington: Government Printing Office, 1873–4.

Specimen Fasciculus of a Catalogue of the National Medical Library under the direction of the Surgeon General of the U. S. Army, at Washington, D. C. By Brevet Lieutenant Colonel J. S. Billings, Assistant Surgeon, U. S. Army. Washington: Government Printing Office, 1876, pp. 72, 4to.

A Medical Report upon the Uniform and Clothing of the Soldiers of the United States Army. By Brevet Major A. A. Woodhull, Assistant Surgeon, U. S. Army. Washington: Surgeon General's Office, 1868, pp. 26, 8vo.

Report on the Pathological Anatomy and Histology of the Respiratory Organs in the Pleuro-pneumonia of Cattle, with 6 lithographs from photo-micrographs. Washington, June 15, 1870. By Brevet Lieutenant Colonel J. J. Woodward, Assistant Surgeon, U. S. Army, pp. 9, 4to. In the Report of the Commissioner of Agriculture on the Diseases of Cattle in the United States. Government Printing Office, 1871.

Report of Results of Examinations of Fluids of Diseased Cattle, with reference to the presence of Cryptogamic Growths. By Brevet Lieutenant Colonel J. S. Billings, Assistant Surgeon, U. S. Army, and Brevet Major E. Curtis, Assistant Surgeon, U. S. Army, pp. 12, 4to. In the Report of the Commissioner of Agriculture on the Diseases of Cattle in the United States. Government Printing Office, 1871.

Photographs of Surgical Cases and Specimens, taken at the Army Medical Museum, with histories of 296 cases. By Brevet Lieutenant Colonel G. A. Otis, Assistant Surgeon, U. S. Army. Washington, 1866–71. 6 vols., 4to.

Reports accompanied by Photographs of Microscopic Objects. By Brevet Lieutenant Colonel J. J. Woodward, Assistant Surgeon, U. S. Army, viz.:

Report on the Magnesium and Calcium Lights as applied to Photo-Micrography. 6 pp., 4to., 11 photographs. Surgeon General's Office, 1870.

TYPHO-MALARIAL FEVER: IS IT A SPECIAL TYPE OF FEVER?

BY
J. J. WOODWARD, M.D.,
SURGEON, UNITED STATES ARMY.

SINCE the earliest times Pestilence has followed in the footsteps of War. It has been the consequence of Ignorance as much as of Necessity. Its causes are to be sought, not merely in fatigues, exposures, and privations necessarily incurred during the performance of heroic deeds; not merely in the morbific influences of strange climates; not merely in the miseries of besieged places; they are equally to be sought in the thousand preventable abnormal conditions to which armies are exposed when huddled together in ill-selected, over-crowded, and filthy camps, fed by ignorance or cupidity on scanty, improper, ill-cooked food, drinking water contaminated by human excretions, and breathing air poisoned by human effluvia. Hence arises a brood of camp diseases more destructive than the improved small-arms or rifled cannon of any foe; which, on memorable occasions in times past, have annihilated whole armies, and yet more frequently decided the fate of campaigns in spite of the military genius of generals or the heroism of their followers.

The humane spirit of modern civilization, revolted at horrors which modern science has shown to be to a great extent preventable, has made of late years earnest efforts at prevention, and the intelligence of modern administration has perceived that the success of such efforts is an indispensable condition to success in war. It is this double motive that has called into existence the Medical Staff, which has become of late years an essential component part of the army of every civilized nation. The work to be done cannot be performed by a band of hired barber-surgeons employed to bind up rudely the wounds received in battle; it cannot be performed by the voluntary assistance of the crowd of educated civil physicians who may be led by motives of humanity to the

scene of suffering, after the mischief is done and pestilence has actually broken out; for its efficient performance it requires the existence of a trained Medical Staff.

To possess the desired efficiency such a staff must be a component part of the army in time of peace. It must enjoy such rank and pay in its higher grades, and offer to its lower grades such prospects of reasonably rapid promotion as to secure the life-long services of the ablest medical men. These must devote themselves in times of peace to the study of the sanitary conditions which affect the health of armies, and war must find them ready to point out with authority the precautions which cannot be neglected without peril. The demands of philanthropy, the impulses of humanity, are best fulfilled by such a staff when it best discharges its military duty, which is to see to it that of a given number of soldiers on the rolls, the largest possible number shall always be ready for duty.

This proper duty of the Medical Staff is as much a military duty as that of the artillery or the infantry. It is the business of these to maim and destroy till the strength of the enemy is so diminished that he can no longer resist; it is the business of those to aid in keeping the fighting ranks full until their work is done. For the efficient discharge of this military duty the medical staff requires military rank as much as any other branch of the army service. It requires it, not merely because it is otherwise impossible to secure the continuous service of an efficient personnel, but because, without military rank, no personnel, whatever its qualifications, can be really efficient. It requires rank, because it requires authority. If its wise counsels can be thwarted at every step by the obstinacy of ignorance, it becomes a mere witness of evils which it is impotent to prevent.

This is not the time or place to discuss the question as to whether the conditions just indicated as necessary to secure the most efficient medical staff possible have yet been completely fulfilled in any army. I must leave that question to the thoughtful consideration of my hearers of all countries. It is enough for my present purposes to point out that coincidently with the elevation of the medical staff in modern times the camp diseases of modern wars have notably diminished in malignancy. We no longer hear of armies destroyed by pestilence within the first few weeks or months after taking the field. The old bubo-plague and spotted typhus no longer figure in the history of wars between civilized nations.

I admit that much remains to be done by Preventive Military Medicine. I admit that much remains to be learned with regard to the causes of disease. But this is no reason why armies should not enjoy to the uttermost the knowledge we already possess. And it is after all but a partial application of this knowledge which has brought about the amelioration to which I have just referred. I think it is safe to affirm that no army ever yet took the field, even in the most modern times, that did not campaign in daily violation of well-established hygienic laws. And hence it will be found that if in any modern war the mortality from disease has been very small, it has been because the struggle has been very brief. We shall deceive ourselves if we overlook the element of time in the production of the diseases of modern armies. An army may very well escape with trifling mortality from an exposure of a few weeks or months to influences which would have proved fearfully destructive if continued for a year or longer.

This was well illustrated by the experience of the Armies of the United States during the civil war by which this country was recently convulsed.

Notwithstanding the want of discipline among the newly-levied troops; notwithstanding the lack of experience in military medicine on the part of the newly-enrolled medical officers; notwithstanding all the faults of administration and the necessity of reform, of which so much has been said in certain quarters, the mortality from disease did not exceed 2.2 deaths per 1000 of strength monthly, during the first six months of the struggle[1]—a death-rate which, if it had continued, would have represented an annual loss from disease of 26.4 per 1000 of strength. But in point of fact a rapid increase in the mortality took place after the first of November, 1861. The deaths from disease during the year ending June 30, 1862, were at the rate of 49.3 per 1000 of strength, and, in spite of increased discipline and increased experience, the reorganization of the Medical Staff, and other reforms, rose to 63.2 per 1000 of strength during the year ending June 30, 1863. During the year ending June 30, 1864, the improved discipline and sanitary management of the white troops were at length accompanied by a diminished mortality, and the death-rate from disease fell to 48.2 per 1000 of strength, or very nearly what it was during the first fiscal year of the war. Subsequently, however, it rose again, in spite of every effort, and was 56.5 per 1000 of strength during the year ending June 30, 1865. These figures, it must be remembered, refer only to the white troops, who constituted the bulk of our forces. They include both the regular army and the volunteer troops. And I may remark that I have shown in the introduction to the first volume of the Medical History of the War,[2] after an analysis of the records of the Surgeon General's office, and a careful comparison with the records of the Adjutant General and the Quartermaster General, that the average annual mortality from disease among the white volunteers, during the four years of the struggle, must be fixed at 55 per 1000 of mean strength, while it was only 32 per 1000 of strength for the small regular army during the same period.

But what shall I say of the mortality among the colored troops? The statistical tables in the first volume of the Medical History show it to have been 211 per 1000 of mean strength during the year ending June 30, 1864, and 139.8 during the year ending June 30, 1865. Even if we extend the view to cover the whole period from the day the first volunteer colored regiment was mustered into service to the day the last was mustered out, a period of five years and four months, and distribute the mortality over the whole term, it will be found, as I have shown in the Introduction to the first volume of the Medical History,[3] that it represents an average annual mortality from disease of 133 per 1000 of mean strength—a proportion which it is impossible to consider without emotion.

It is only just to express my conviction that a large part of this excessive mortality was due to circumstances from which the colored men suffered before they were enlisted, rather than to mismanagement or maltreatment afterwards. It must be remembered that a large part of these colored soldiers were fugitive slaves. They fled into our lines literally naked and starving. The diseases which destroyed them were to a great extent engendered by the miseries they had suffered before they found a refuge under our flag.

[1] These figures and those in the following paragraphs are deduced from the Statistical Tables of the first Medical volume of the Medical and Surgical History of the War of the Rebellion (1861–5). Washington, Government Printing Office, 1870.

[2] Op. cit., Introduction, p. xli.

[3] Op. cit., Introduction, p. xl.

In all—embracing in the count all arms and all colors, officers and men—the total mortality of the armies of the United States from disease during the war (including the deaths during the year following, in which a large part of the mortality was from diseases contracted during the struggle), may be fixed at a little over 200,000 men, while battle and wounds destroyed rather more than 100,000.[1] This estimate of 200,000 men dead of disease embraces, it must be remembered, not only about 30,000 of the colored soldiers, upon whose mortality I have commented, but a nearly equal number of white soldiers, who died while prisoners of war in the hands of the enemy, under circumstances upon which I refrain from comment at this time, but for which the Medical Administration of the United States army can assuredly in no wise be held responsible.

These circumstances no doubt increased the mortality of our armies greatly beyond what it would otherwise have been. On the other hand, it must not be forgotten that discharges from the service for disability took place with a freedom—perhaps in strict justice I ought to say, with a recklessness—never before exhibited in any army. The total number of soldiers thus discharged may be estimated as not far short of three hundred thousand.[2] No doubt very many of these men only went home to die. No doubt, also, many thousands of them, epecially those suffering with lame backs and general debility, rheumatic pains, and cardiac palpitations, needed only a short sojourn in a northern climate, with a generous diet, to have fitted them again for the field. I cannot dwell here on this shameful story. It is one of the scandals of the war. I have never been able to collect data to justify even an approximate estimate of the proportion of these men who died. I believe it to have been comparatively small. Removed from the theatre of war, returned to the healthier circumstances of their homes, I doubt not that a large proportion of these men recovered their health, and that thousands of them, induced by the large bounties which were offered for recruits, found their way again into the ranks.

Certainly the statistics I have cited afford food for earnest thought. But if their study is to be profitable, it must be undertaken with a careful consideration of all the circumstances. Above all, when these figures are compared with the results of other wars, the element of time must be taken into account, or the gravest misunderstandings will arise. A striking illustration of this possibility has been brought to my notice.

In an oration delivered on the 2d of August, 1874, on the anniversary of the Military Medical School of Berlin,[3] Professor Rudolph Virchow,

[1] In the Introduction to the first Medical volume of the Medical and Surgical History of the War, I have fully discussed the various official records, and arrived (see p. xxxviii.) at the following results, which are probably very near the truth:—

Deaths from battle, wounds, and other violence	93,969
Deaths from disease	186,216
Deaths, the causes of which are not recorded	24.184
	304,369

On the reasonable supposition that those deaths in which the causes are not recorded were distributed between wounds and disease in the same proportion as those whose causes are recorded, we shall arrive at the results expressed in the text.

[2] See Introduction to the first Medical volume just cited, p. xlii.

[3] Die Fortschritte der Kriegsheilkunde, besonders im Gebiete der Infectionskrankheiten. Rede gehalten zur Feier des stiftungstages der militar-ärztlichen Bildungs-Anstalten, am 2, August, 1874, von R. Virchow. Berlin, verlag von A. Hirschwald, 1874.

one of the ablest medical thinkers in Europe, alluded to this enormous mortality from disease during our war, and contrasted it with the comparatively small losses of the German army during the late war with France. After reciting the American figures, and, I may add, after speaking of the publications of the Surgeon General's office in language so complimentary that, as one of the officers concerned in their preparation, my modesty will not allow me to repeat it, the distinguished orator continued as follows: "The German army had, during the last French war, out of a strength of 913,967 men, a total loss of 44,980. Of these, 17,572 fell before the enemy, 10,710 died later of their wounds, 12,253 fell a sacrifice to disease and pestilence; certainly a very favorable proportion. But we had before us the experiences of two recent wars, which had been well discussed and taken advantage of, both scientifically and administratively. We possessed the inestimable experience of the Americans, and, finally, we had German science."[1]

Truly, I will not yield even to Virchow himself in my appreciation of German science. I know well the debt of gratitude which modern medicine owes to German investigation. For myself, I have drawn much of the knowledge I value most from German sources. I admire German science for its industry, which is without parallel; for its originality, which has already pushed discovery so far; but most of all, for the truly catholic spirit which knows no nationality, and for the manly independence, which never hesitates to weigh authority by a comparison with the actual facts.

Something of this spirit I have tried to catch, and I will not therefore allow myself to be misled as to the matter under discussion, even by the authority of Virchow. I cannot avoid interpreting the facts otherwise than he has done, and I feel that I am but performing a necessary duty when, standing here before you to-day, I declare it to be my opinion that not even German science would have sufficed to save the German army from a greatly increased percentage of mortality if the war had lasted a few years instead of a few months.

The figures given by Virchow are from the official report of Dr. Engel.[2] They represent a period of seven months. They must not be compared with the losses of our whole civil war, but with the losses of the first seven months. Let us make the comparison. Virchow's figures represent a mortality of 13.4 + per 1000 of strength for seven months, or 1.9 + per 1000 monthly. Now I have already shown you that the mortality from disease in our armies during the first six months of the war averaged 2.2 per 1000 monthly. During the following month, viz., November, 1861, the mortality increased very greatly, so that, indeed, almost as many died during that month as during the whole six months preceding. Including these deaths, I find, on a discussion of the official data, that during the first seven months of the civil war, viz., from May 1 to November 30, 1861, the mortality from disease was at the rate of 18.8 per 1000 of strength, or 2.7 per 1000 monthly.[3] You see that the

[1] Op. cit., S. 7.

[2] Zeitschrift des Königlich Preussischen Statistischen Bureaus. Redigirt von dessen Director Dr. Ernst Engel. Zwölfter Jahrgang, 1872. Berlin, 1872, S. 293.

[3] These ratios are deduced from the Statistical Tables in the first Medical volume of the Medical and Surgical History quoted above. I may add here, that the total number of deaths from disease from the commencement of the war to November, 1861, recorded on the alphabetical registers of the Surgeon General's Office, is 3206. There are also 160 deaths recorded during the same time, the causes of which are not specified. If we sup-

mortality of our army from disease, during equal times, was really but about one-third greater than that of the German army in the French war; whereas, as Virchow presents the subject, it is made to appear more than fifteen times greater.

Now, I am perfectly willing to admit that a part of the actual difference in favor of the German army was really due to better discipline and a wiser application of preventive medicine. But I do not believe that this is the only reason for the difference. The raw levies of the Northern States were sent at the very first to the South, and campaigned or lay in camp during the time in question in the miasmatic valleys of the Mississippi, the Ohio, and the Potomac, while the German army did its work on the comparatively salubrious plains of France. What would have happened had the scene been exchanged? How much of the difference was really due to the wisdom of man, how much to a more favorable climate, and the absence of the intense malarial poison to which all were exposed who bore our arms?

This malarial influence, and the pathological processes to which it gives rise, demand the most careful study of those who would endeavor to comprehend the problem of the health of armies in America. It is not merely manifested by the frequency of ordinary ague, of which very nearly a million cases[1] were officially reported in our armies during the war; it colors and complicates other diseases to an extent which can hardly be credited by those who have not been eye-witnesses to its effects. Especially does it demand the consideration of those who may attempt the study of the fatal continued fevers which have been, and will be, the

pose all of these to have been deaths from disease, the number will be 3366. Of this number, 1457 died during the month of November, viz.: 1413 of disease, and 44 of causes not specified. The absolute number is but a little more than one-fourth of the German figures; but the average strength of the troops in service during the time referred to was also about a fourth of the German army, so that the ratios are as stated in the text. The comparatively small mortality at the commencement of our civil war is strikingly illustrated by the Medical History of the three-months' volunteers. It will be remembered that at the commencement of the struggle President Lincoln called out 75,000 men to serve for three months. This call was issued April 15, 1861. According to the records of the Adjutant General's Office, the actual number of men who were mustered into service on this call was 91,816. Through the kindness of Assistant Adjutant General T. M. Vincent, I have ascertained from the death and disability records of the Adjutant General's Office that the actual mortality of these troops during their three-months' service was as follows:—

Deaths from battle, wounds, and other violence	221
" from disease	151
" from causes not recorded	231
Total	603

If all the deaths of which the causes were not recorded were from disease, the total number of deaths from disease would be 382, or 4.2 per 1000 of strength for the three months. This would correspond to a mortality of 1.4 per 1000 monthly, or less than three-fourths of the monthly rate which I have shown in the text for the first six months of the war.

[1] The number of cases and deaths reported as due to ague was as follows:—

	White Troops.		Colored Troops.	
	Cases.	Deaths.	Cases.	Deaths.
Quotidian intermittent fever	447,258	452	63,992	58
Tertian intermittent fever	375,170	381	51,045	54
Quartan intermittent fever	41,223	84	3,923	15
Congestive intermittent fever	13,673	3,370	2,536	794
Total	877,324	4,287	121,496	921

The grand total for both white and colored troops is 998,820 cases, and 5208 deaths. See the first volume of the Medical History, cited above.

scourge of the camps of every army that operates in the valleys of the Mississippi and its tributaries, or of the rivers that flow into the Gulf of Mexico, and into the Atlantic ocean south of the fortieth parallel.

These camp fevers occupy a conspicuous place among the diseases which produced the mortality of our armies during the civil war. They caused more than one-fourth of all the deaths from disease. In fatality they proved second only to diarrhœa and dysentery. I suppose it is safe to estimate that diarrhœa and dysentery produced about 60,000 deaths in the armies of the United States during the civil war, and camp fevers rather more than 50,000.[1] A right comprehension of these two groups of diseases must therefore be regarded as the most important task of Military Medicine in America.

It is my purpose in the present discourse to discuss certain points connected with the pathology of these camp fevers, and especially the complication of the typhous process by the malarial influences to which I have just referred.

Already in the fall and early winter of 1861 reports began to come in from various quarters that a new form of fever was prevailing in our camps. The great majority of our army surgeons at that time were fresh from civil life. Many of them had been engaged in extensive private practice. Almost all of them were well acquainted with ordinary typhoid fever (enteric fever, typhus abdominalis) as it annually prevails in the Northern States, and it was precisely these men who first called attention to the fact that the fevers they were now called upon to combat differed in many important particulars from those to which they were accustomed at home.

This circumstance was noticed in both the Western and the Eastern armies; but, so far as I have been able to ascertain, official attention was first directed to it in the Army of the Potomac, then encamped just beyond the banks of the river in front of Washington. By an order from the Adjutant General's office, dated December 6, 1861, a Board of Medical Officers was convened for the purpose of visiting the camps of the Army of the Potomac, and inquiring into the nature of the prevailing fever, especially endeavoring to ascertain—to use the language of the order appointing the Board—"whether it is to be considered an intermittent or bilious remittent fever in its inception, assuming in its course a typhoidal type, or a typhoid fever primarily." This Board consisted of Surgeon A. N. McLaren, U. S. A.; Brigade Surgeon G. H.

[1] 44,558 deaths from diarrhœa and dysentery were reported during the war, out of 156,885 deaths from disease, the causes of which were specified in the reports. If we suppose these diseases to have caused the same proportion of those deaths from diseases the causes of which are not specified in the reports, we shall obtain the estimate of the text. The cases and deaths of the several forms of camp fevers reported to the Surgeon General's Office were as follows:—

	White Troops.		Colored Troops.	
	Cases.	Deaths.	Cases.	Deaths.
Typhus fever	2,501	850	123	108
Typhoid fever	75,368	27,056	4,094	2,280
Common continued fever	11,898	147	......	......
Typho-malarial fever	49,871	4,059	7,529	1,301
Remittent fever	286,490	3,853	30,645	1,002
Total	426,128	35,965	42,391	4,691

This gives a total of 40,656 deaths from these fevers out of 156,885 deaths from disease, the causes of which are specified in the reports. On the supposition just mentioned we obtain the estimate in the text.

Lyman, U. S. Volunteers, and Assistant Surgeon M. J. Asch, U. S. Army. It convened December 16, at the quarters of Brigade Surgeon Lyman, who was chief medical officer of the division commanded by General Fitz John Porter; and during its subsequent labors examined the hospitals of this and other divisions, and collected a great deal of valuable information, in writing, by means of written questions addressed to the brigade and regimental medical officers of parts of the army which its members were unable conveniently to visit. As might have been expected, some diversity of opinion was expressed in the replies received. But in their general tenor the great majority of these replies confirmed the opinion formed by the members of the Board on the basis of their own personal observations. This opinion was that, while a certain number of cases of ordinary typhoid fever existed in the army, the large majority of the febrile cases were "bilious-remittent fevers, which, not having been controlled in their primary stage, have assumed that adynamic type which is present in enteric fever."

In the following spring, after the Army of the Potomac commenced its Peninsular campaign, this mixed form of fever increased in frequency. It assumed formidable proportions during the siege of Yorktown, and reached its greatest intensity while the army lay encamped on the swampy borders of the Chickahominy. The hospitals of Washington and Alexandria, of Baltimore, Philadelphia, New York, and other Northern cities, were crowded to overflowing with the sick. Among the attending physicians were some of the best instructed medical men of the Northern States. They have shown that they recognized that they had to deal with an unusual pathological complex, by perpetuating the name of Chickahominy fever, which appears so often in their reports.

It was under these circumstances that I was ordered, early in the summer of 1862, to serve on a Board of Medical Officers, who were directed to revise the form of sick report in use in the army. I was fresh from the Army of the Potomac, which I had accompanied from its camps before Washington, where I had spent the winter with it. I had lain in camp at Yorktown, and followed the army up the Peninsula. I had formed the opinion that the prevailing fevers of the Army of the Potomac were hybrid forms, resulting from the combined influence of malarial poisoning and of the causes of typhoid fever. I believed that individual cases received their characters in accordance as the one or the other of these influences preponderated in the individual, and that very often the picture was still further complicated by the coexistence of a scorbutic taint. Full of these opinions, I proposed to the Board, as I had previously suggested to the Surgeon General, to designate the complex condition in question by the name typho-malarial fever, and I induced the Board to add this term to the list of diseases printed on the blank form for the monthly sick report. I often regret that I did not also urge upon the Board the preparation of a circular letter to accompany the new sick report, explaining why this term had been adopted, and calling for special reports with regard to the cases which it was intended to designate. As it was, the term went upon the sick report without any explanation or a word of comment. But even under these circumstances, 23,346 cases were reported as typho-malarial fever during the following year, showing how widely the opinions I had formed were shared by the medical officers of the army.

In September, 1863, I published in Circular, No. 15, of the Surgeon

General's Office,[1] a short statement with regard to the sickness and mortality of the army during the first year of the war, in which I stated the meaning I designed to attach to the term typho-malarial fever, and in November of the same year completed the publication of my Outlines of the Chief Camp Diseases of the United States Armies,[2] in which I presented my views at some length. I also gave a short account of the subject in Circular No. 6, Surgeon General's Office, 1865.[3] And now, after a careful study of all the pathological and documentary material accumulated during the war, I still hold substantially to the same views, and hope in the second volume of the Medical History of the War to present the facts upon which my opinion is based in such a manner as to command universal assent. In so doing, I shall, of course, present many additional matters of detail not contained in any of my former publications; and also, I may frankly say, I shall correct some errors of detail (particularly with regard to the pathological anatomy of the intestines in these fevers), into which I fell during my earlier studies, and which were incorporated in the account presented in my book on Camp Diseases.

In the same connection I hope to present historical proof of a proposition, which I do not hesitate even now to announce to you, that such hybrids between malarial fever and typhus, of one form or another, are no new thing in the history of armies. They were not first begotten on American soil. In fact, in every great army that ever yet campaigned for any length of time in a malarial region the prevalent form of fever has been a hybrid between malarial fever and some form of typhus. By a malarial region I mean simply a region in which ague and remittent fevers are the common endemic diseases. The causes of these fevers act always with peculiar intensity upon strangers; and an invading army is, therefore, peculiarly prone to suffer from them. At the same time the uncleanliness and overcrowding of camps favor the spread of some form of typhus, whether originating *de novo* or introduced from without by contagion. In some cases it has been spotted typhus which has made its appearance; in others it has been abdominal typhus (typhoid fever), and as the typhus poison has been of one or the other variety, and as the malarial influence has been more or less intense, the complex result has varied—at times the malarial phenomena, at times the typhous phenomena being the more prominent. The morbid conditions resulting from these twofold causes have usually also been still further modified by the existence of actual scurvy, or at least of a scorbutic taint, the result of an improper and often scanty supply of food.

It would be impossible, in the time allotted to me, to re-examine to

[1] Circular No. 15, Surgeon General's Office, Washington, D. C., September 8, 1863. Sickness and Mortality of the Army during the First Year of the War. The language used in this preliminary report was as follows: "Moreover, while a certain amount of uncomplicated enteric and remittent fever certainly did occur, especially at the commencement of the war, the vast majority of the camp fevers of the army were of a mixed character, exhibiting undoubted enteric phenomena, variously combined with the periodicity and other peculiarities of malarial disease, and still further modified by the tendency to incipient scurvy, which is the ordinary concomitant of camp diet. To indicate this mixed nature, the term typho-malarial fever, which I had the honor to suggest to the Department in June, 1862, appears appropriate, and, at the present time, is coming into very general use."

any great extent the history of armies from this point of view. I can only bring to your notice a few striking illustrations. First, let me recall the pestilential fever which destroyed the French General Lautrec and the army of thirty thousand men with which he besieged Naples, in 1528. Hecker[1] has analyzed the chronicles of the time with his usual eloquence, and has arrived at the conclusion that it was simply petechial typhus which raged in the French camp. After an examination of the authorities he cites, I cannot agree with this conclusion. The siege began May 1. Almost the first act of the French General was to cut the aqueducts which supplied the city with water. By this rash act the plains on which he was encamped, intensely malarial at the best, were converted into a vast series of bogs and stagnant pools, from which the heat of the sun raised clouds of vapor, which hung around his camp like a pall. I must believe that Jovius[2] was right in attributing the destruction of the French army chiefly to this act of madness. No contemporaneous physician has described the pestilence that followed, but the chroniclers of the siege have recorded symptoms which are incompatible with the theory of Hecker. Jovius tells us that many of the patients were affected with swellings of the belly and legs. They became so pale and death-like in their complexions that their friends were hardly able to recognize them. Scarcely able to crawl, and without attendants to nurse them, they often died in their tents of hunger and thirst. Sandoval[3] describes the same death-like faces, and applies to them the epithet *amarillos* (yellow). These are not the symptoms of spotted typhus, but of intense malarial poisoning. We saw just such cadaverous yellow faces, with swelled legs and bloated bellies, crawling about in the camps at Young's Point on the Mississippi, and at other swamp-beset localities, during our own war.

I agree, however, with Hecker, to whose work I must refer you for particulars, that spotted typhus was no doubt also present in the camp; and I suppose it complicated the acute fevers very much, as it did later in the same century in the Austrian armies in Hungary. Moreover, Guicciardini[4] relates that after Lautrec first fell sick, during the month of July, things fell into confusion, the enemy cut off the convoys of provisions, and some of the soldiers actually died of starvation in consequence. These circumstances, I doubt not, also played their part in destroying the French Army. By the second of August there were but four thousand men fit for duty. Lautrec died August 15, and, the mortality still continuing, his successor thought only of flight. This he attempted August 29, but was pursued, and capitulated at Averse a few days later. Crowded into the stables of la Madeleine, the pestilence continued its ravages among the prisoners, and when, a little later, they were released by the conqueror, but a handful remained to find their way back to France.

Next let me ask your attention to the story of the celebrated Hunga-

rian fever, which for at least three centuries played so formidable a part in the campaigns undertaken by the House of Austria against the Turks. The valleys of the Danube and its tributaries are still the home of agues, remittent and continued malarial fevers, big spleens, and malarial cachexias. Lying further to the north than our own Mississippi valley, the climate is nevertheless such that the marshy borders of the streams and pools give rise to a malaria scarcely less intense than that with which we are familiar in the lower Mississippi. I may refer you to the papers of Müller, Wenmaring, and Lántz[1] for graphic descriptions of the characteristics of the country and of its prevailing diseases in our own day.

Now, in every considerable campaign against the Turks, in which the armies of the German Emperors invaded the Hungarian plains, from the beginning of the sixteenth century to the end of the eighteenth, a form of fever prevailed among the troops so unlike the ordinary European fevers that it has always been known as the Hungarian fever, and so fatal as to occasion the proverb that "Hungary is the grave of the Germans." This Hungarian fever has exercised some of the best medical minds of the last three centuries. It is now generally admitted to have been a hybrid between the endemic remittent fevers of the Hungarian soil and spotted typhus. The attention of civilized Europe was first directed to it when, after the luckless Hungarian campaign of Maximilian II., in 1566, his pest-stricken soldiers returned to their homes. They scattered the contagion of spotted typhus throughout Germany on their way. The disease bred by that contagion was also called the Hungarian fever, but it was simply spotted typhus, and the student of the voluminous older literature of the Hungarian fever finds no little confusion growing out of this circumstance, and no little difference between the descriptions of such eye-witnesses as Thomas Jordan and Tobias Cober, who described the Hungarian fever as they saw it on Hungarian soil, and the descriptions of those who merely observed the spread of spotted typhus in the German towns, and gave it the name of the Hungarian fever because the contagion had been spread by soldiers returning from Hungary.

The army of Maximilian, however, was not the first German army which had suffered from the Hungarian fever. In 1542 a pestilential fever broke out at the camp before Ofen, in the Imperial German army which Margraf Joachim von Brandenburg had led against the Turks. It became still more fatal during the disastrous retreat, and according to Hæser[2] destroyed 30,000 men. Johannes Langius,[3] who accompanied the Count Palatine, Frederick II., in this campaign, as well as in the

campaign of 1526,[1] has left an epistle, in which he describes this fever in such a manner as to leave no reasonable doubt of its identity. He tells us, also, that the camp surgeons, whose ignorance he pictures with bitter sarcasm, gave the disease the name of Bhreüne (Bräune) on account of the condition of the tongue, which they supposed to be the most essential symptom. According to Hæser,[2] the Chronicler Wintzenberger gave the same epidemic the name, "pestartige Bräune." These names long continued in use among the designations by which the Hungarian fever was known to the vulgar.

The epidemic of 1566 is famous both on account of the manner in which typhus was spread through Europe by the disbanded soldiers, and on account of the classical description of the Hungarian fever by Thomas Jordan,[3] who accompanied the army of Maximilian as his chief medical officer. The spring had been exceedingly wet, and the great Hungarian streams had overflowed their banks; the summer was unusually hot and dry; the German army was scantily supplied with food. When the fever first appeared the army was encamped at Komorn, at the point of junction of the Waag and the Danube—a marshy, intensely malarial plain. It became still more destructive in the camp at Raab, where the Raab and Rabnitz empty into the Danube. Such was the devastation caused by it that Maximilian, though his force when he went into camp at Raab was about 80,000 men, did not venture to take the offensive, and saw the gallant little garrison at Zigeth captured by the Turks after more than twenty vain assaults, without daring to strike a blow in their behalf. In the early autumn he ignominiously retreated with the remains of his army. After the retreat the pestilence was especially destructive at Vienna. The hospitals could not accommodate all the sick, and the dead and dying were scattered through the streets. Throughout all this devastation it was the German troops that suffered; the native Hungarians almost entirely escaped.

The Hungarian fever broke out anew during the siege of Papa, in the year 1597. The Italian allies suffered most. According to Hæser, of more than 8000 of these troops, less than 1500 found their way back to Italy. This is the epidemic described in the admirable work of Tobias Cober.[4]

Again it made its appearance, as we learn from Esslinger and Hæser, among the 12,000 German troops who occupied Hungary under the celebrated General Montecucculi,[5] in the year 1661. The disease broke out in the swampy camp between Komorn and Neuhäusel, and soon brought the fruitless campaign to an end.

Once more it appeared in the army with which Prince Eugene besieged Belgrade in 1717. The Grand Vizier advanced to the relief of the besieged with a great army. The Turks took the offensive, and shut up Eugene, with his army of 60,000 men, in the marshy plain between the Danube and the Save. It was here that the Hungarian fever broke out,

accompanied by a fatal dysentery. A large number of men had perished, when the gallant Prince, venturing all on the fortunes of a day, attacked the Turkish army and routed it after a desperate battle. The surrender of Belgrade followed, and the peace of Passarovitz was the result.

Still more terrible were the ravages of the Hungarian fever during the disastrous campaign which the Emperor Joseph II. undertook against the Turks in 1788. Disappointed with regard to the help he had anticipated from Russia, and his troops decimated by pestilence, the feeble campaign terminated in a humiliating retreat. The imperial army at the commencement of the season numbered about 200,000 men; its losses from disease have been estimated at between 30,000 and 40,000.

The symptoms of the Hungarian fever have been described at great length by numerous writers. I can only refer to a few leading points. The patients were seized, usually during the afternoon or evening, with a slight, short chill, followed by a burning fever. This was accompanied by a headache so intense that the vulgar called the disease sometimes the head disease (Haupt-krankheit); the raging brain disease (Hirntobende-krankheit); or the head misery (Kopfwehe). So prominent was this symptom that in the earlier autopsies medical men sought for the cause of the affection chiefly in the encephalon, and, deceived either by the congested appearance of the choroid plexus, or by the presence of vermiform clots of blood or fibrin in the ventricles or in the great sinuses, actually supposed they had discovered worms in the brain, and gave to the disease the designation "Cerebri vermis" or "Hirnwurm." With the headache came on a pain in the epigastrium so intense that the appellations "Herzbräune" and "Herzbreun," were widely employed. Soon the fever was accompanied by a raging delirium; the tongue became dry and covered with a brown coat, from whence the vulgar names "Bräune" and "pestartige Bräune," already mentioned. Hemorrhages from the cracked tongue or from the gums were common. Then, there was also the characteristic typhus eruption of the skin, accompanied by petechiæ, whence the disease was called "Febris Lenticularis," especially by the Italian physicians. In cases which recovered, the favorable crisis usually occurred on the fourteenth or twenty-first day, but fatal cases often terminated much earlier. In some cases gangrene of the extremities occurred.

All these symptoms, together with the unmistakable contagion, certainly point to spotted typhus; but from a very early period, cultivated physicians, like Sennertus, for example, have pointed out that this fever differed in several marked particulars from ordinary spotted typhus. The most striking differences were its tendency to present a decidedly remittent type in its earlier stages, and the accompanying gastric symptoms, bilious vomiting and the like. Even Rulandus,[1] who was disposed to identify the disease with the febris lenticularis of the Italians, was obliged to admit that during its early days it frequently presented, in a decided manner, the type of a simple or double tertian fever. A com-

[1] Martin Rulandus. De Morbo Ungarico. Leipsic, 1610. Consult Cap. I. p. 9, where, after intimating that these remissions are deceptive in their character (falsa specie), the author admits that in the case of Baron Reinhard, who died of the Hugarian fever, he supposed, during the earlier history of the case, that he was dealing merely with a double tertian. For his argument in favor of the identity of the Hungarian fever with febris lenticularis, see Cap. VIII., § XX. p. 376. Consult further, Cap. VIII., quæstio 39, p. 510, for argument against the supposition that the Hungarian fever has truly a tertian or quartan type.

mon form was the semi-tertian, to which the old Greek physicians gave the designation Hemitritæus; and hence the Hungarian fever has sometimes been described as the Hemitritæus Daciæ.

So marked were these symptoms that Sauvages, the great Nosologist,[1] classes the "Amphimerina Hungarica," as he calls it, among the remittent fevers. The learned Naumann[2] goes so far as to declare that the Hungarian fever is at the bottom merely the common summer fever which occurs every year in Hungary, the valley of the Danube, and Southern Russia, and attains malignity only in epidemic years. Among modern epidemiologists, while Ozanam[3] still clings to the notion that Hungarian fever was merely typhus, both Hecker and Hæser[4] express the opinion that it was typhus, modified by the intense malaria of the Hungarian plains.

Side by side with the Hungarian fever a chronic affection occurred among the German soldiers in Hungary, which, like the Hungarian fever, was often spoken of as the Hungarian disease. (Morbus Hungaricus, or Lues Pannonica.) This was the celebrated Languor Pannonicus, or Asthenia Pannonica.[5] It was a profound debility, accompanied with a disgust for food, unwillingness for exertion, diarrhœa, and pains in the back. It attacked large numbers of men, and not unfrequently proved fatal. I suppose it to have been the joint effect of chronic malarial poisoning and a scorbutic taint. Much in the old descriptions reminds me of a certain group of cases of general debility which were common enough in our own war. These, too, were rebellious to treatment so long as the patient remained in the malarial region, but recovered promptly, like some of the cases of Languor Pannonicus described by Tobias Cober, so soon as the patients escaped to a healthier atmosphere and better diet.

Dysentery was another camp disorder which proved fatal in the Hungarian campaigns. It is mentioned by various writers, as for example, by Cober, but does not appear to have attracted as much attention as it probably deserved.

I cannot dwell further in this discourse on the story of the Hungarian camp diseases. I have said enough to indicate that the chief difference between these diseases and those of our own camps during the war of 1861–5 consisted in the prevalence of spotted typhus in Hungary instead of abdominal typhus, which was the form from which our armies suffered. The degree of malarial complication must have been very similar. The extent to which any scorbutic complication existed is difficult now to ascertain. Almost all the writers complain of the food and cooking of the Hungarian camps; but the soldiers would appear to have had fresh meat in some abundance, for one of the constant complaints is that they persisted in cooking it too soon after killing. Scurvy, of a marked kind, however, does not appear to have occurred, and the most significant evidence of the frequent existence of a scorbutic taint is, after all, the constant development in every army, after a few months' campaigning, of numerous cases of the Languor Pannonicus.

[5] For a description of the Languor Pannonicus, see particularly the work of Cober, cited above. Consult, also, Sauvages, op cit., tom. i. p. 802.

Of late years we have heard but little of this once dreaded scourge, which only now and then attracts the attention of some medical writer whose tastes incline to historical studies. I cannot but believe, however, that whenever a German army goes again into the valley of the Danube, as perhaps may happen before long unless the present disturbances in the Danubian provinces are fortunately brought to a peaceful termination, the old Hungarian plague will once more appear in its ranks—a more formidable foe to be encountered than the sword of the Turk.

I have thus presented to you a couple of striking illustrations of the hybrid disease resulting from the complication of malarial influences with the causes of spotted typhus. Let me next refer to some examples of the similar complication with typhoid fever.

The first instance to which I shall refer is the epidemic of the so-called morbus mucosus, which occurred at Göttingen during the years 1760–61, and which has become famous, less on account of the extent of the mischief done than because of the admirable description which we owe to two teachers in the Medical Department of the Göttingen University, Röderer and Wagler.[1] The summer of 1760 was warm and rainy; the winter which followed was wet, with notable vicissitudes of cold and mild weather. Besides the inhabitants, a garrison of French troops, numbering, with the camp followers, about 8000, was shut up in the town. Röderer and Wagler have drawn a striking picture of the want of food, the uncleanliness, the general misery that prevailed. Already by the middle of July, 1760, intermittent fevers, sometimes of mild type, sometimes, however, of marked malignity, occurred to a degree unusual in that region. During August the intermittents continued to be prevalent, but malignant forms became more numerous, and many of the cases assumed a continued type. At the same time a malignant dysentery made its appearance, and raged with fatal results till the month of November. The intermittents meanwhile had continued, but during the month of November both these and the dysenteries were gradually replaced by the morbus mucosus, which became the prevailing disease, and continued as an epidemic all winter. During April and May, 1761, it was again, to a great extent, replaced by intermittents, but still scattered cases continued to occur during the summer. In the autumn, intermittents again became the common disease, occurring often in a malignant form; and smallpox, which had first appeared during the summer of 1761, assumed epidemic proportions during the winter of 1761–2.

The mucous fever was a continued fever, which in severe cases was often prolonged beyond the twenty-first day, sometimes till after the thirtieth, though fatal cases often perished as early as the ninth. In its earlier stages it usually presented a decidedly remittent type, tertian, double tertian, or semi-tertian being the most common varieties. Sometimes, as the patients convalesced, the continued fever passed into an ordinary intermittent before recovery took place. After the fever was fairly under way it presented many of the symptoms of ordinary typhoid fever. Delirium, frequent, feeble pulse, diarrhœa, meteorism, in the worst cases petechiæ, made their appearance. At the beginning the tongue was furred, and its swollen, red papillæ projected through the fur; it became brown and dry as the disease progressed. Hemorrhages

[1] J. D. Röderer et C. G. Wagler. De Morbo Mucoso. Göttingen, 1762.

from the nostrils sometimes took place, especially about the sixth day; still more frequent were hemorrhages from the bowels. It is a significant fact that the extract of Peruvian bark often proved highly efficacious in those cases in which the remissions were most marked.

The disease derived its designation from the belief that an excessive secretion of mucus from the alimentary canal was its most characteristic phenomenon. This was manifested by the frequency with which mucous vomiting, with or without bile, occurred at the inception of the cases, just as we know it does in ordinary remittent fever. The diarrhœa was interpreted as but another expression of the excessive mucous secretion, and the dead lumbricoid worms which were often noticed in the stools, or during the progress of autopsies, were supposed to have been bred in consequence of the morbid excess of mucus in the alimentary canal. In the autopsies, the closed glands of the stomach and small intestines were usually found tumefied to a marked degree. This was erroneously supposed to be the consequence of an accumulation of the mucous secretion in their interior. Röderer and Wagler have published three remarkable copper etchings of the appearances they observed. The lesions they have figured are not those characteristic of typhoid fever, but of ordinary intestinal catarrh. In one of the autopsies (No. V.) they describe the agminated glands, near the ileo-cæcal valve, as marked with black pigment, quite like the condition often observed in our own war, and described as "the shaven-beard appearance." The mesenteric glands were enlarged. The anatomical evidences of peritonitis were often present. Dysenteric sloughs frequently existed in the colon. Nowhere, however, do I find any description of the bulky tumefaction, ulceration, and sloughing of the glands of Peyer, which is characteristic of typhoid fever. Nevertheless, I am by no means sure that this essential lesion did not exist in some of the cases at least. It must be remembered that the typhoid lesion was not then known as we know it now. Perhaps some of the gangrenous spots, of smaller or greater size, which our authors describe as having been observed in the small intestines of some of their cases, were really of this nature.[1] This appears to me the more probable, because in the case of the very similar epidemic which Sarcone[2] observed in Naples in 1764, and which, in the circumstances under which it occurred, its course, symptoms, and the anatomical lesions observed after death, appears to have been identical with the morbus mucosus of Röderer and Wagler, I read that these gangrenous spots were again observed in the alimentary canal of some cases, and that they occurred chiefly in the small intestines. But even if this interpretation is correct —and I believe it is—I cannot think that the characteristic typhoid lesion was present in all the cases in which Röderer and Wagler made autopsies, or it surely would have received greater attention from those acute observers, and I must think that in part, at least, of their cases, there was no other lesion of the small intestine than a smart intestinal catarrh.

The doctrine of the mucous fever, as taught by Röderer and Wagler, took firm root in the medical mind of Europe.[3] It figures largely in

[1] Op. cit., p. 162.

[2] Michael Sarcone. Istoria ragionata dei mali osservati in Napoli, nel corso dell' anno 1764. Naples, 1764. There is a German translation by Fuesslin, Zurich, 1772, and a French translation by Bellay, Lyons, 1804. Our library contains the German translation only.

[3] Ozanam, op. cit., tome i., p. 257 et seq., gives an excellent abstract of the works of Röderer and Wagler, and of Sarcone.

many of the text-books of the first half of the present century, and you will even find the descriptions reproduced without criticism, under the head of "Mucous or pituitous fever," in the admirable Dictionary of Copeland.[1] Some writers have expressed the opinion that this mucous disease was after all neither more nor less than ordinary typhoid fever.[2] I cannot agree with them. I see in the story, as told by the original observers, unquestionable marks of malarial complications; indeed, also of scorbutic complications. I do not marvel that the Göttingen observers should have devoted sections of their work to the discussion of the relationship of the mucous disease with intermittent fever, and of its relationship with scurvy, and should have arrived at the conclusion, to use their own striking language, that the epidemic which they observed was the corrupted and degenerate progeny of intermittent fever. They thought they saw also a causal relationship between intermittent fever and dysentery, an opinion which I cannot discuss here, but which I must confess I share to a certain extent. No doubt, since their time, the term mucous fever has often enough been applied to simple typhoid fever, and although of late it has been banished from the books, it still survives among certain practitioners who were educated thirty or forty years ago, and I myself have heard it applied by old practitioners to unmistakable cases of typhoid fever within the last five years. The misuse of terms in medicine is, however, a common consequence of imperfect knowledge, and we must not allow ourselves to be led astray by it.

I cannot dwell longer now upon this interesting epidemic. Let me turn next to another illustration, in which the malarial element was still more potent, and with regard to which I need only present a few salient points, because it is so often cited in connection with the diseases of armies that most of the leading facts must be well known to you all. I refer to the Walcheren fever, which decimated an English army in the year 1809.

The previous experience of English armies in the Netherlands had shown the malignant character of the malarial influences which prevail in that region. It had been described in striking language in the excellent work of Sir John Pringle.[3] He had recorded that all the flat region between the rivers Lys and Scheldt and the sea, was marshy and unhealthful, the home of periodical fevers; that a great part of Holland, including Dutch Brabant, was subject to the same disorders, and that the air was worst of all in Zealand. He has left graphic descriptions of the fevers which prevailed among the English troops operating in these low countries between 1742 and 1748. He had observed especially that when the troops were encamped near stagnant waters the "marsh fevers are not only apt to begin with little remission, but, after intermitting for some days, to change into continued fevers of a dangerous nature."[4] Especially was this the case during the summer and autumn of 1748, when the troops were encamped near the inundations of Dutch Brabant. An epidemic of such fevers occurred among them. Pringle writes: "At the height of the epidemic it appeared that both intermittents and remittents, by extending or doubling their paroxysms, frequently changed

into a continued and dangerous form, and that most of those we lost died in this way. These men, as we remarked, had a corrupted smell for a day or two before their death, and soon after, their bodies putrefied. Some had petechial spots, though the place where they lay was neither crowded with sick nor too close; and to these spots were added some other symptoms, the same with those of the hospital fevers."[1]

The expedition of 1809 renewed the experiences of Pringle on a more formidable scale. The English army, of between 42,000 and 43,000 men, was quite healthy when it set sail from the Downs, July 28, but as early as the middle of August the number of the sick was so great as to excite alarm. By the 26th the number was 5000. By the 7th of September it amounted to 10,948. According to Sir Gilbert Blane,[2] 26,846 men were sent to hospital in Zealand between the 21st of August and the 18th of November. The expedition was paralyzed by these misfortunes, and after the surrender of Flushing, August 15, was unable to continue offensive operations. In spite of the fact that a large part of the sick who were sent home to England began to improve so soon as they escaped from the pestilential regions in which their diseases had originated, and ultimately recovered, the total mortality was large. It has been estimated at about 8000 men. I must refer you to Hansard's Parliamentary Debates, the Annual Register, the Edinburgh Review, and the Essays of Marshall, Sir Gilbert Blane, Dawson, Davis, and Wright,[3] for the particulars of this disastrous expedition. I can only pause to emphasize a few facts.

The diseases of the Walcheren expedition were diarrhœa, dysentery, intermittents, and a form of fever which began as a remittent, and subsequently assumed a continued form, and which at that time was designated the Walcheren fever, or the Walcheren remittent. Sir Gilbert Blane, who visited the island of Walcheren during September and October, reported to the Government "that he found so great a proportion of the sick to consist of those affected with the intermitting and remitting fevers peculiar to marshy countries, that there could be no doubt that the sickness of the army was owing to that cause." He admits, however, that he found a certain number of cases of a fever which he called "typhus," and of dysentery, particularly at Flushing, where "the prevalence of these two diseases was very remarkable, particularly in one regiment, of which all the medical officers were either absent or dead, and of which the sick, originally affected with the endemic disease, were suffering also from typhus and dysentery in consequence of the want of cleanliness, as well as of proper medicines, diet, and attendance."[4] Borland and Lempriere,[5] two other medical officers serving with the

[5] J. Borland and W. Lempriere. Report on the prevailing Malady among his Majesty's Forces serving in the Island of Walcheren. The Med. and Physical Journal, vol. 23 (1810), p. 183.

troops on the island, reported, in the same spirit, that the malady was "the endemic fever of marshy countries; the effect of miasmata from a soil the most productive in deleterious exhalations of any perhaps in Europe;" stated that it prevailed also among the natives of the island as an intermittent or remittent fever, and that among the British troops it assumed "a character of greater malignancy."

But the most elaborate studies of the Walcheren fever were made by the medical men whose duty it became to treat the sick who were sent home to England. Dawson[1] tells us that the Walcheren soldiers were affected with intermittents in a number surpassing those who were attacked by the continued fevers; that many of the soldiers who were subjects of the continued fever had already labored under the intermittent, and that on the other hand intermittents were common among those who had recently recovered from the continued fever. Davis,[2] whose account of the fever is more elaborate, tells us that at the beginning it assumed the quotidian, tertian, double tertian, or quartan type, but that the most common of all was the double tertian. It assumed, however, the characters of a continued fever of typhoid type as it progressed, with muttering delirium, small rapid pulse, dry, black tongue, sordes-covered teeth, fetid odor, and black discharges from the bowels.

On account of the frequency with which this fever was associated with dysentery, the characteristic lesions of dysentery were frequently found in the colon during the autopsies which were made. But Davis[3] has also recorded the significant fact that "the ileum and jejunum were frequently interspersed with tubercles, inflamed and ulcerated in different parts." This description would seem to indicate beyond doubt that the lesions, which we have now learned to recognize as characteristic of typhoid fever, were frequently present in the cadavers of those who had perished from the Walcheren disease. After a thoughtful study of the evidence, no doubt is left in my own mind that this fever was not, as has often been asserted, simply a malignant remittent, but that it was a genuine hybrid between malarial and enteric fever.[4]

Did time permit, I might bring forward other interesting illustrations from the history of the British Army in the East and West Indies and elsewhere, from the Algerine experience of the French, and from other sources; but I fear that I have already occupied too much of your time with facts of this class. I cannot, however, leave the subject of the experiences of other armies without bringing to your notice an unexpected corroboration of the views I am urging upon your attention, which I find in an essay published by Virchow in 1871 on the fever and dysentery of the German army[5] during the recent war with France, which he contrasts with the similar diseases of our own civil war, as described by me in my book on Camp Diseases, and in Circular No. 6. Virchow hesitates to acknowledge "typho-malarial fever" as a special

[3] Op. cit., p. 192.

[4] Essentially the same opinion with regard to the Walcheren fever has been expressed by J. J. Levick. Miasmatic Typhoid Fever. American Journ. of the Med. Sciences, April, 1864, p. 409.

[5] R. Virchow. Kriegstyphus und Ruhr. Virchow's Archiv., Bd. LII. (1871), S. 1. Note pp. 5 and 30.

group of diseases, and exclaims, with cautious conservatism: "It seems to me we ought to be very careful in this direction." Yet, in the same essay, while contending that the prevalent fever of the German army was simply abdominal typhus, as proved by numerous *post-mortem* examinations made at Berlin on soldiers brought back sick from the front, this cautious but acute observer finds himself compelled by the facts under his eyes to use the following emphatic language:—

"Nevertheless, abdominal typhus affords such numerous diversities in its course that it is in the highest degree imperative to preserve every precaution in the interpretation of individual cases. Especially does the admixture (Zumischung) of the malarial element, which also in this war has shown itself active, by numerous cases of intermittent fever, confuse the picture of the so-called normal course of typhus in a sometimes very deceptive manner."

Now, I must protest that these words represent the very essence of the doctrine I am here to defend, and if the comparatively mild malaria of the plains around Metz was capable of complicating the course of the abdominal typhus which occurred in the German army to a sufficient extent to justify this eloquent language, what think you would the great pathologist have written could he have observed for himself the fevers of our own army in the valley of the Mississippi or by the banks of the Chickahominy?

I have occupied the greater part of my hour with these preliminary matters; but not, let me hope, in vain. I come now to a rapid sketch of the principal facts with regard to the typho-malarial fever of the civil war of 1861–5.

The characters and distribution of the malarial fevers of the region in which that colossal struggle took place have been described in a most original and interesting work by our countryman, Dr. Daniel Drake,[1] who has embraced them under the general designation of autumnal fevers. This term serves very well to express the greater prevalence of intermittents and remittents during the autumn months; but it must be distinctly understood that their occurrence is not limited to these months. In the regions in which they are endemic, they may occur at any season of the year, and their course can by represented by a curve in which the abscissas begin to lengthen early in the spring, and grow longer and longer, till they attain their maximum most generally at some time during September or October, after which the curve rapidly drops to a minimum during the winter. Sometimes the curve presents, also, a slightly irregular elevation during the early spring, justifying the term vernal intermittents, which has often been used; but most generally the increasing frequency of these fevers in the spring simply represents the commencement of the annual rise in the curve which culminates in the autumn. This is well illustrated by curves which I have had constructed to represent the monthly number of new cases of agues and remittents reported in our armies in the Atlantic and Central regions during the civil war. These I hand you for examination, but I cannot pause to discuss them at this time. Doubtless the winter and vernal cases are to be regarded in part as relapses, in part as illustrations of the postponed development of the consequences of previous

[1] Daniel Drake. The Principal Diseases of the Interior Valley of North America. Cincinnati, 1850. The same, second series, edited, after the death of the author, by S. H. Smith and Francis G. Smith. Philadelphia, 1854.

exposure; but, however you may choose to interpret them, I wish to insist upon the point that they occur with much greater frequency than some of the systematic writers would have us believe.

Dr. Drake has shown that in a general way these fevers are most intense in the States that border on the Gulf of Mexico, and gradually diminish in frequency and severity as we go to the north, so that they no longer prevail in epidemic form beyond the 44th parallel, and cease to occur even sporadically at about the 47th. To the southwest, the Cordilleras of Mexico and the Southern Rocky Mountains constitute their boundaries, while in the higher latitudes they cease on the great plains, long before we reach the mountains. On the Atlantic slope they prevail with constantly increasing severity as we go southward from New York, and though they do not occur on the table-lands and higher ground of the Appalachian chain, yet they ascend high up the valleys of the streams which flow out of the flanks of those mountains.

In the volume of the Ninth Census of the United States, which is devoted to Vital Statistics,[1] there is an interesting map which exhibits the distribution of the mortality from intermittent and remittent fevers during the year 1870. Doubtless this mortality, which is but at best incompletely represented in the Census Report, can only be regarded as a very imperfect measure of the frequency and severity of these fevers; but, imperfect as it is, its indications are valuable. It shows in a general way the almost complete exemption of New York, the New England States, and the mountainous parts of Pennsylvania, Maryland, West Virginia, and Virginia, and a gradual increase in severity indicated by an increasing mortality in the river valleys as we go southward from the fortieth parallel. It illustrates, also, in a striking manner, a fact which arrested the attention of Drake,[2] that in various scattered districts, from the influence evidently of strictly local causes, the malarial fevers display greater prevalence and malignancy than they exhibit further south and on a lower level.

It would be altogether foreign to my purpose to enter in the present discourse into any discussion as to the causes of these fevers. I simply urge upon you to-day the great fact of their endemic existence, in some localities more frequently and with greater severity than in others, formidable even to the natives of the soil, but still more formidable to strangers, throughout the whole region in which our great armies operated during the civil war. The characters of the fevers thus distributed are too well known to you all for any description to be necessary here. I need only remind you of the frequent occurrence throughout the Southern States, side by side with ordinary ague, of malignant forms, the so-called congestive chills or pernicious fever; of the severity of the remittent fevers which prevail; of the frequency of big spleens, disordered livers, and malarial anæmias, and of the great frequency with which, in these regions, an intermittent type is impressed on the ordinary acute phlegmasiæ, and even on chronic disorders.

Drake has also presented an interesting account of the distribution throughout the United States of typhoid or, as he calls it, typhous

[1] Ninth Census, vol. ii., Vital Statistics of the United States. Washington, 1872. See, also, Statistical Atlas of the United States—based on the results of the Ninth Census, 1870. By F. A. Walker, 1874; in which the map in question is given on a larger scale, and better engraved, as Plate 42.

[2] Op. cit., First series, p. 704.

fever.[1] This fever is the usual form in which typhus manifests itself in the United States. The spotted typhus of the Old World never appears on our soil except as isolated cases, imported, as "ship fever," into our seaports. Drake has correctly pointed out that while in a general way the typhoid fever of the United States is more prevalent in the Northern than in the Southern States, it nevertheless does occur both sporadically and in local epidemics even in the southernmost portion of our territory. This fact is strikingly illustrated by a map in the volume of the Ninth Census already referred to, which[2] represents the distribution throughout the United States, during the year 1870, of some 24,000 deaths from typhoid fever. In constructing the map a few hundred cases of cerebro-spinal fever were included, but their number is too small to vitiate its value[3] in illustrating the distribution of typhoid fever during the year in question. This map, while exhibiting in a general way a gradual decline in the mortality from typhoid fever as we go to the South, displays also a number of limited areas of high mortality, representing the endemic prevalence of the fever during that particular year in certain localities. Several of these areas of local prevalence are situated in the Southern States. In one of them, in Georgia, which embraces the region drained by the Altamaha and Satilla rivers, typhoid fever caused about one-fifth of all the deaths—a greater mortality than it produced in any part even of the New England States. In another almost equally remarkable area, embracing parts of the States of Mississippi and Alabama, having near its centre the town of Columbus, Mississippi, the proportionate mortality from typhoid fever was nearly as great.

Drake has urged, as one of the distinguishing marks between typhoid fever and the autumnal fevers, that the former is not limited like the latter to a particular portion of the year, "between the summer and winter solstice, but occurs, though unequally, at every season." But he believes that "on the whole, however, they are most prevalent in autumn and winter,"[4] an opinion which has been shared by several careful writers.[5]

Liebermeister[6] has recently compared the statistics of the monthly prevalence of typhoid fever in some of the great European cities, and shown that in London, Berlin, and Basle, the curve which represents the course of the disease is distinctly autumnal in character. "The minimum is in February and April (in the Berlin curve a little later); the maximum is in September and October. (In Berlin, the maximum is in October.)" Munich alone presented an exception, the maximum falling in February. Now, I must say, my study of the sick reports of our civil war inclines me to believe that the autumnal curve observed by Liebermeister represents also the usual annual distribution in this country. I have constructed curves representing the monthly ratio of new cases to strength in each of the three regions. These curves present certain irregularities in the Atlantic and Central regions corresponding to the

[1] Op. cit., Second Series, p. 358 et seq.

[3] Ninth Census, vol. ii., cited above. Special tables of Mortality, p. xxiii. The number of cases is, enteric fever, 22,187; typhus fever, 1770; cerebro-spinal fever, 650. The cases reported as typhus were simply misnamed, and are to be regarded as enteric.

[4] Op. cit., 2d series, p. 358.

[5] See, for example, G. B. Wood. Treatise on the Practice of Medicine. 6th ed. Philadelphia, 1866, vol. i. p. 383.

[6] Liebermeister. Typhoid Fever, in Ziemssen's Cyclopædia of the Practice of Medicine, Amer. transl., vol. i. New York, 1874, p. 65.

varying circumstances in the fortunes of the great armies, but on the whole they represent the disease as most prevalent during the latter part of the summer and autumn, rather than during the autumn and winter. In the Pacific region the curve is strictly autumnal. The maxima are as follows: October in 1861, September in 1862, November in 1863, September in 1864, October in 1865. The minima were in April and May for 1862 and 1863, April, 1864, and March, 1865. In the Atlantic region the maximum for 1861 was in November. In 1862 there were two maxima, one during the Peninsular Campaign in July, followed by a great reduction on the withdrawal of that army, and a second maximum in October and November. In 1863 and 1864, the maxima were during July and August. In 1865, during October. The minima fell in March, 1862; June, 1863; February, 1864; and April, 1865. In the Central region the maximum for 1861 fell in November; in 1862, in May. During 1862 the curve was quite irregular; it rose to a maximum in May, then diminished in frequency during the summer, and steadily increased after September through the winter, attaining its maximum in February, 1863, after which it diminished until June, and then again increased to a second maximum in August. The maximum for 1864 fell in September; in 1865, during September and October. The minima were in March and September, 1862; June, 1863; February in 1864 and 1865.

I find from the Annual Reports of the Board of Health of the city of Boston, for 1874 and 1875, that the mortality from typhoid fever during those years pursued a markedly autumnal course, the maximum being during September in 1874, and during October in 1875.[1] In the District of Columbia the registration returns show that the greatest number of deaths since 1872 have always occurred during the months of August and September.

I incline, therefore, to the belief that typhoid fever presents in fact in this country an annual autumnal curve very similar to that of the so-called autumnal fevers. I base upon this circumstance no argument as to the relationship or nature of either disease, but press it upon your attention as a fact which must not be overlooked.

Next, let me remind you of the important fact that intermittent and remittent fevers often disappear more or less completely from neighborhoods in which they have long prevailed, and are replaced by typhoid fever. This circumstance could not escape such a faithful observer as Drake. He has described it in the following language:—

"Far in the North, remittent fever often presents, almost from the beginning, a tendency to the continued type, displaying the characteristics of the synochus of Cullen's Nosology. It is properly called autumnal fever, because it prevails most in that season, and is an equivalent for the true remittent fever of the warmer climates. Nearly the same remark is applicable to this fever when, in the middle latitudes, it appears in the long-cultivated and drier portions of Tennessee, Kentucky, Western Pennsylvania, and Ohio. Formerly it often abated into an intermittent; latterly, it is apt to degenerate into a continued type."[2]

Whatever criticism you may choose to bestow on the wording of some

[1] See Second Annual Report of the Board of Health of the City of Boston, 1874, and Third ditto, 1875. Both volumes give charts representing the weekly mortality from typhoid fever. Also, Annual Reports of the Board of Health of the District of Columbia for 1872, 1873, 1874, and 1875.

[2] Drake. Op. cit. First Series, p. 781.

parts of this remarkable passage, it is an honest attempt by a keen observer to describe a class of facts which he had had the opportunity of observing on a great scale. The substantial truth, that in numerous districts throughout this land intermittents and remittents were the prevailing form of fever when the first settlements were made; that as time passed by and cultivation progressed, the intermittents diminished in frequency, the remittents exhibited more and more a disposition to pass into continued forms, and finally were replaced by ordinary typhoid fever, which became the prevailing epidemic fever—all this, I suppose, has occurred under the personal observation of many of the American physicians who listen to me to-day, and I need not weary you by multiplying authorities in proof of a fact with which you must all be familiar.

But next let me observe that the change thus effected is not always a permanent one. Often in individual years the intermittents and remittents reappear in epidemic-wise in regions such as I have just described, and then the typhoids vanish for a time, to return once more when the temporary prevalence of the periodical fevers comes to an end.

Existing thus side by side, replacing each other in this intimate—if you will, in this intricate manner—it is evident that the unknown causes of the periodical fevers, and of typhoid fever, whatever they may be, must frequently coexist. Ought we not, then, to anticipate that individuals exposed to both would often suffer with fevers in which phenomena belonging to both affections would also coexist?

I suppose the once popular belief that diseases are entities, and that a man can suffer from but one at time, is now so completely dead that it is quite unnecessary for me to bring forward facts and arguments to disprove it. I suppose it to be now well established that individual cases of disease are always more or less complex, representing in every instance the total effect of all the morbific causes acting upon the individual, and modified always by his individual resisting power, the result of his own individual organization and his own previous history. Even Sauvages, the greatest of all the systematic nosologists of the last century, already recognized this fundamental fact when he exclaimed, in the introduction to his work: "Genera and species of diseases are abstract notions. Throughout the universe neither genera nor species exist, but only individuals."[1] Is it wonderful, then, that hybrid forms of disease, exhibiting the ordinary symptoms of malarial and of typhoid fever, variously combined, should long have been observed in this country? In fact, such hybrid forms have long been observed in Europe also. In the first volume of his Institutes, published in 1781, Burserius[2] recognized them as a group; "the Proportionata," which he defines as a compound species composed of the synochus and intermittent fever. This union, he says, occurs especially "when intermitting fevers prevail epidemically, or at least constitute the prevailing and stationary disease; for then almost all diseases bear some resemblance to intermittents, or sporadic, or intercurrent fevers, of whatever other kind, are combined with the intermitting fevers."

Hermann Schmidt,[3] in his account of the so-called Summer fever, which was epidemic throughout Europe during the year 1827, has still more

[1] Sauvages. Nosolog. Method., Amsterdam, 1768, vol. i. p. 26.

[2] J. Bapt. Burserius. Institut. Med., vol. i., Milan, 1781. I quote ftom Hecker's edition, Leipsic, 1826, vol. i. p. 512.

[3] Hermann Schmidt. Uber des Europæische Sommerfieber, Paderborn und Arnsberg, 1830.

elaborately described as the form of fever then most generally prevailing, a combination of intermittent fever with the endemic typhus of Europe (our typhoid fever). He has subdivided the resulting hybrid forms into two chief classes: 1. *Typhus intermittens subintrans*, which he defined as a combination of typhus and intermittent fever, with a predominance of the typhus element. 2. *Febris intermittens typhosa*, which he defined as a similar combination, with a predominance of intermittent fever. I would refer you to his elaborate treatise for many suggestive details.

Naumann[1] has quoted, with approval, the views of Burserius and Schmidt, and mentions corroborative observations by several other writers, to which I might add many more did the scope of this discourse permit.

Recurring to the American experiences, I would recall to your memory the fact that the existence of the hybrids under consideration did not escape the practical eye of Drake: "When remittent fever terminates fatally in one or two weeks," he observes, "a certain amount of subsultus, a dryness of the tongue, and intestinal hemorrhage, are sometimes present, although no typhus fever may be prevailing in that locality, and this brings us to inquire, not into the distinctive peculiarities of these two forms of fever, but into their combination, into the hybrid or mongrel diathesis which results from the joint impress, in ever-varying proportions, of the causes which produce true typhous and true remittent fevers."[2] For these hybrid forms he proposes the designation, "Remitto-typhous or secondary typhous fever." "I do not recollect," he says, "to have seen a case of fever well-marked as typhous in the early stages terminate as an intermittent, nor a decided intermittent degenerate into a typhous. The union is between remittent and typhous." And this certainly is the most common combination; but the combination with intermittent does also occur, though less frequently, and both the possibilities which Drake tells us he never observed were seen often enough during the civil war.

The same combination of remittent and typhoid fever which was observed by Drake has also been described by the late Professor Dickson of this city. Dickson continually emphasized the doctrine of the frequent blending of those febrile types which are "connate in cause and analogous in symptoms." He tells us that "it is a matter of familiar remark, that in long-protracted cases of the ordinary remittent of malarious regions, there is a domination of the palpable contrast or alternation of the period of febrile exacerbation and unison—a tendency in the former to continuousness, the latter being less an alleviation of the symptoms—and the several symptoms themselves approaching more and more in appearance those which belong to simple continued fever, nervous fever, or typhoid fever. In common professional language, such cases 'take on the typhoid character.'" "On examination, typhoid lesions will sometimes be found in the body dead of bilious remittents. The mucous membrane of the stomach and intestines is highly injected in severe and short attacks. In more protracted cases, follicular ulceration may be found throughout the whole extent of the bowel."[3]

[1] Op. cit. Bd. III., Abth. ii., S. 235.
[2] Drake. Op. cit., Second Series, p. 556.
[3] Samuel Henry Dickson. Elements of Medicine. Philadelphia, 1855, p. 196. See also his Essay On the Blending and Conversion of Types in Fever. Trans. of the Amer. Med. Association, vol. v. (1852), p. 127.

Similar opinions were long entertained by my revered preceptor, Dr. George B. Wood. He has told you that remittent fever "is sometimes of a low, adynamic or typhous character from the commencement. This may be the result of a previous exposure to causes calculated to depress the vital powers and to deprave the blood; but it probably most frequently arises from the co-operation of a typhoid epidemic influence with miasmata." He did not believe that the characteristic lesions of typhoid fever ever occur in pure remittents, as some have reported, and explained their observations by the remark that "there is reason to believe that enteric fever has sometimes been mistaken for bilious or remittent fever, and lesions belonging to the former been placed to the account of the latter; and not unfrequently, in all probability, the two diseases are in greater or less degree mingled together."[1]

Now, under the conditions which existed in the camps of our armies during the late civil war, these hybrid combinations, which had already attracted the attention of such men as Drake, Dickson, and Wood, in civil life, made their appearance, as might have been predicted, on a great scale, and produced, as I have already shown, a formidable mortality. It was for these hybrid forms that I proposed the term typho-malarial fever. I never meant this term to represent a specific type of fever, but intended it to designate all the many-faced brood of hybrid forms resulting from the combined influence of the causes of malarial fevers and of enteric fever. The term corresponds essentially to the "Proportionata" of Burserius. It includes both the "Typhus intermittens subintrans" and the "Febris intermittens typhosa," of Herman Schmidt, and the "Remitto-typhous" of Drake. These are merely varieties of the group of hybrids, all of which I intended to embrace. I pointed out, in my book on Camp Diseases, that this whole group might be conveniently divided, for the purpose of study, into—1. Fevers in which the malarial element, without being the only pathological condition present, is the predominant one; and, 2. Fevers in which the typhoid element is evidently predominant, although the others are also present in a more or less distinct manner. To these I felt compelled to add a third group, namely, "Fevers of either of the first two varieties, in which from the first, or at some time during the progress of the affection, the scorbutic element becomes predominant." To this general grouping of the cases, with all the light of subsequent experience, I must still substantially adhere.

In the group of cases in which the malarial phenomena predominated, the disease began as a simple intermittent or remittent fever, of quotidian, tertian, or quartan type, the most frequent form being a simple or double tertian; but after a week or ten days the fever assumed a more or less completely continued type, with many of the phenomena characteristic of typhoid fever, such as diarrhœa, abdominal tenderness, meteorism, muttering delirium, subsultus tendinum, dry, brown tongue, and the like. But even when the typhoid phenomena were most pronounced, some of the most characteristic of them were often wanting. Thus, sometimes there was no diarrhœa at all, but constipation instead. The characteristic tache rouge, or rose-colored eruption, was generally entirely absent; gastric disturbance, hepatic tenderness, and an icteroid hue of the countenance were much more generally present than in simple typhoid fever.

[1] Wood. Op. cit., vol. i., pp. 307 and 309.

Now, a large proportion of these cases terminated favorably, especially, as I think, because quinine was so freely used in their treatment; the occurrence of ordinary paroxysms of ague was a frequent accident during the convalescence. And, just because of the frequency with which they recovered, I suppose, the number of autopsies in cases of this kind which I have been able to collect is much less than in cases of the second group, of which I shall presently speak. Still, I have collected a number of autopsies of cases of this kind, in which diarrhœa had been present during the fever, and in which, after it had assumed a continuous type, it had strikingly resembled typhoid fever, but in which dissection showed no other lesion in the alimentary canal than a smart intestinal catarrh. Patches of inflammation, scattered irregularly throughout both small and large intestines, and enlargement of the closed glands, often associated with pigment deposits, were the characteristic lesions. The solitary glands of the small intestine appeared as little projecting tumors the size of pinheads, which often had constricted necks, so that they resembled tiny polypi. The agminated glands of Peyer, slightly prominent, were often the seat of pigment deposit, which gave them the so-called shaven-beard appearance. Sometimes the villi of the small intestines were hypertrophied; sometimes they had pigment deposits at their apices. In the large intestine the slightly swollen solitary glands were often the seat of pigment deposits, seated either in the glands alone, or sometimes also in the surrounding mucosa, in which case the central dot of pigment was surrounded by a little pigmentary ring. When the fever had supervened, as often happened, upon a chronic flux, or where dysentery had been developed during the course of the fever, or of the convalescence, and had been the immediate cause of death, the characteristic follicular ulcerations of the colon or the phenomena of the diphtheritic process complicated the picture. Great enlargement of the spleen and congestion of the liver, with or without fatty degeneration, were frequent concomitants. The condition of the intestinal canal in these cases closely resembled that which has been emphasized by Röderer and Wagler, and by Dickson. Between the simple inflammatory enlargement of the closed glands, which I have pictured, and the more luxuriant process which occurs in ordinary typhoid fever, and which most pathologists believe to be specific, every possible transition existed. I, for one, confess myself unable to draw a line between the two conditions. Anatomically they appear to pass into each other by insensible gradations. The essential element of both is the accumulation of a swarm of migrated white corpuscles in the closed glands, in the surrounding lymph passages, and the adjacent connective tissue, associated, doubtless, as we must infer from the study of other inflamed tissues, with multiplication of the lymph cells of the parenchyma of the closed glands by division, though it is difficult, if not quite impossible, to demonstrate this latter phenomenon in the present case. The sloughing and ulceration of the so-called typhous process is, I think, sufficiently well explained by the intensity of the process and the nutritive disturbances which thence result, without conjuring up in our imaginations an undemonstrated specific something to account for it.

The group of cases in which the typhoid phenomena predominated more closely resembled ordinary typhoid fever. They began more like it; they ran their course like it; like it, they refused to be cut short by quinine; after death they presented the characteristic lesions of the patches of Peyer. But even these cases presented, also, many phenomena

which did not belong to ordinary typhoid fever. First of all, I must emphasize the manifestation of an unwonted tendency to periodicity. This was not merely an exaggeration of the daily exacerbation and remission, which we all know as a part of the history of the early stages of typhoid fever. The exacerbations assumed with great frequency a tertian or double tertian type, which has no parallel in the ordinary typhoid history. With this tendency to periodicity, the gastric and hepatic disturbances common in remittent fever were often associated in the early stages, and ordinary ague paroxysms often occurred in the convalescence. The autopsies in these cases disclosed the ordinary lesions of typhoid fever. During my earlier studies I believed that I had observed certain peculiarities in the character of the ulcers in these cases, by which they might be distinguished from the lesions of simple typhoid.[1] A larger experience, especially the examination of a large number of specimens received by the Medical Section of the Army Medical Museum, has convinced me that this opinion was premature. I renounce it as erroneous. There is really nothing in the lesions of Peyer's glands, in these cases, to distinguish them from ordinary cases of typhoid fever; and it was just these lesions, so well known to you all that I need not pause to describe them, which were observed in the vast majority of those fatal cases of fever occurring during the late war in which autopsies have been recorded or specimens preserved. As for the other lesions observed in these cases, tumefaction of the spleen, far beyond the degree ordinarily observed in typhoid fever, was common enough, and the pigment deposits in various tissues and organs, which are so frequent in malarial diseases, were very often encountered. Moreover, the colon lesions, characteristic of chronic fluxes or of acute diphtheritic dysentery, were frequently associated, as is well shown by numerous specimens in our Museum.

I will not for a moment, however, countenance the sophism that, because the lesions of ordinary typhoid fever were those most frequently encountered during the war in fatal cases of fever, uncomplicated typhoid fever was the prevailing febrile form. On the contrary, as I understand it, though this was the lesion in the majority of fatal cases, the slighter lesions described in connection with the first group were those which most probably existed in the majority of the cases which recovered. Nor will I admit the fallacy that, even in those fatal cases in which the typhoid lesion was most marked, the patients are thereby proved to have died of simple typhoid fever. I will not emphasize the big spleens, pigmentary deposits, or other anatomical evidences of malarial complication. I will even admit the uncertain diagnostic value of all these phenomena in the present state of our knowledge. But I cannot ignore the facts of clinical observation. I cannot but see in the periodicity and other clinical evidences of malarial complication to which I have briefly alluded, proof of the action of an additional morbid agency, to which I doubt not we must look for one reason of the great mortality of the fever cases in our armies.

It often happened that, in fevers belonging to either of the classes I have just described, scorbutic phenomena complicated the picture, and sometimes even took a commanding place in determining the course and issue of the disease. I have affirmed, and shall elsewhere bring forward satisfactory evidence in proof of the assertion, that a mild but distinctly recognizable scorbutic taint was wide-spread among our

[1] Camp Diseases, p. 102.

soldiers. It manifested itself as a peculiar anæmia, accompanied by muddy complexion, large, smooth, flabby tongue, and by neuralgic or pseudo-rheumatic pains in various parts of the body, especially in the back. As a rule, it was only after this scorbutic anæmia had existed for some time, either alone or variously complicated with symptoms due to malarial poisoning, that the characteristic scorbutic conditions of the gums, the scorbutic indurations about the joints of the lower extremities, and the well-known scorbutic purpura made their appearance. These easily-recognizable symptoms of fully-developed scurvy were but moderately frequent. The preliminary anæmia, however, was common enough, though often overlooked or misunderstood.

Now, when either of the forms of typho-malarial fever, which I have described, occurred in individuals suffering under the scorbutic taint, the symptoms were modified to a degree corresponding to the intensity of the scorbutic condition. The effect of the complication was to increase the tendency to mental and bodily prostration during the disease, to tardy convalescence subsequently, and to increase the frequency of petechial and purpuric eruptions, and of hemorrhages from the nose and bowels. Sometimes the characteristic scorbutic condition of the mouth was developed during the progress of the fever, when it had not previously made its appearance. When the characteristic typhoid process was developed in individuals laboring under a marked scorbutic taint, the symptoms closely resembled those of spotted typhus. Fatal hemorrhages from the bowels were common in such cases, and on the dissection, the lower patches of Peyer were found converted into dark-red or black pultaceous sloughs of considerable size and thickness. I suppose the scorbutic condition to have modified the typhoid ulceration in such cases, just as we often see it modify the condition of superficial ulcers or of gunshot wounds.

The outlines of the chief phenomena of typho-malarial fever which I have thus endeavored to present to you to-day are necessarily incomplete, for it is, of course, impossible to go into the details of so large a subject in a paper like this. I hope to be able to fill up these outlines in a satisfactory manner in the second volume of the Medical History of the War.

And this brings me, at length, to answer the question—Is typho-malarial fever a special type of fever?—and I reply, unhesitatingly, that it is not. I, at least, am free from the blame of that error, if any one has fallen into it. In my first published account of typho-malarial fever, I expressly denied that it could be regarded as a new disease. "Much rather," I said, "should it be considered simply as a new hybrid of old and well-known pathological conditions, in which the exact train of symptoms is as variable as the degree of preponderance attained by each of the several concurring elements."[1] And this is the view which I advocate to-day. The essential point which I desire most to impress upon you is the recognition of the group of hybrids between typhoid fever and the malarial fevers. The scorbutic complication was a mere accident of the war; its existence is by no means essential to the idea of typho-malarial fever, but in dealing with the typho-malarial fever of the war I could not omit it from the picture.

It was, and still is, my belief that the mixed forms of fever which I have thus sketched constituted the great majority of the continued

[1] Op. cit., p. 111.

fevers of our army during the civil war. I still, however, adhere to the opinion which I expressed in Circular No. 15 of 1863, and in Circular No. 6 of 1865, that simple typhoid fever and simple remmittent fever did also occur, though the statistics fail to show to what extent; and I still adhere, also, to the view then expressed, that a large portion of the cases actually reported during the war "as typhoid and remittent fevers are, to a great extent, to be regarded simply as those in which the typhoid or the paroxysmal phenomena predominated."

It would follow, from the views I have advanced, that typho-malarial fever ought to be encountered also in civil life, particularly in our Southern States; not, indeed, to the same extent that it existed during the war, when hundreds of thousands of soldiers, born and bred in the Northern States, campaigned in the malarial valleys of the South, but to an extent which deserves thoughtful recognition. And this, I must believe, from my own observations, and from facts communicated by professional friends in various parts of the South, is actually the case.

Since the close of the civil war my doctrine of typho-malarial fever has been accepted with approval in many quarters, and the term has been extensively used. Dr. Meredith Clymer[1] has adopted it as a synonym of "American Camp Fever" in his edition of Aitken's Science and Practice of Medicine. Dr. George B. Wood,[2] though unwilling to adopt the name, has fully recognized the great prevalence during the civil war of "this mixture of the two fevers." In the sixth edition of his work on Practice of Medicine, published in 1866, he remarks: "Since the last edition was published this complex affection has been much more prevalent than before, probably because great numbers of young men engaged in the armies at an age when the predisposition to enteric fever is strongest, have been in an unusual degree exposed to the joint action of the causes of the two fevers; to that of enteric fever, in the almost unavoidable filth attendant upon great encampments, and to that of bilious remittent or intermittent in the low grounds from which miasmatic effluvia are so abundantly extracted in our Middle and Southern States in the latter part of summer and in autumn."

Dr. Austin Flint,[3] whose former experience in the South makes me regard his opinion in this matter as particularly valuable, in his Treatise on the Practice of Medicine, has adopted the term typho-malarial fever as a convenient designation to represent the hybrids which had been indicated by Drake and Dickson, and which Flint himself tells us he has recognized in his own lectures to medical classes for twenty-five years. His article on simple remittent and typho-malarial fever is an admirable one, to which I refer you with pleasure.

With this intelligent corroboration and support of my views on typho-malarial fever, there has been, I must admit, some indiscriminate use of the term, which is well calculated to bring it into discredit. I have myself known it to be erroneously applied to simple typhoid fevers, in the clinical history of which I at least could see nothing to indicate a malarial complication, and to simple remittents in which I could perceive no typhoid symptoms. I think I have observed, also, a tendency in certain quarters to bestow the term upon almost any obscure febrile affec-

tion which offered diagnostic difficulty. May I not hope that the publication of this paper may serve to diminish abuses of this kind hereafter?

But although widely accepted, my views with regard to typho-malarial fever have not escaped criticism. Dr. Roberts Bartholow,[1] formerly an Assistant Surgeon of the Army, and now a successful practitioner in Cincinnati, has attacked them with a good deal of acrimony in an article on the Camp Fevers of the Civil War, which he contributed to the Medical Volume of the Memoirs of the United States Sanitary Commission. Led away by the energy of his attack, he goes so far as to affirm boldly "a *typh* element did not in my experience exhibit itself as a modifying condition in remittent fever." He declares the camp fevers of the army to have been remittent, simple continued, typhoid, and typhus, and affirms that "these several forms of fever preserved as distinct clinical features in the army as the same forms of disease in civil life." To give force to his criticism, he even goes to the extent of misrepresenting my views, and says: "There were, therefore, according to Woodward, really no cases wholly typhoid, or wholly remittent, in the army"—although I had distinctly affirmed the occurrence of such cases in all my publications on the subject. I will not pause in this place to answer these criticisms of Dr. Bartholow in detail. I would merely remark that, although he makes typhus one of the forms of camp fever, he himself admits that he has no knowledge of it from personal observation. And though he is so ready to deny that the *typh* element, as he calls it, can complicate malarial fevers, he is compelled to concede that the malarial influence can complicate typhoid fever. This he has explicitly affirmed to be a common occurrence in civil life, in another article contributed to the same volume of the Memoirs of the Sanitary Commission. His language is: "I have already adverted to the fact that, as populations increase in malarious districts, typhoid supplants the intermittent and remittent fevers. During the transition period a mixed fever prevails; it is a typhoid fever with a malarial complication."[2] He admits, therefore, the combination of malarial and typhoid fevers, but holds that the typhoid element is always dominant. Against this, I maintain that sometimes the one and sometimes the other of the two elements predominates, and I must believe that the facts are on my side. I may add that the distinguished editor of the volume of Memoirs in question, Dr. Austin Flint, felt himself called upon to append to Dr. Bartholow's essay the following remark: "The general favor with which the term typho-malarial has been received, and the readiness with which it has come into vogue, show that it expresses a pathological doctrine consistent with clinical experience."[3]

In his hasty criticism, Bartholow falls into another error—so mischievous, that I cannot permit it to go unchallenged. He denies the frequency of a scorbutic taint among our soldiers during the civil war, and thinks that even the cases reported as actual scurvy include many of "ordinary stomatitis." He says: "In a pretty extended course of observation, I did not meet during the war a single well-marked case of scorbutus."[4] A general belief that Bartholow's opinions as to this matter are correct would be a serious obstacle to any attempt to improve the alimentation of our soldiers in any future war. In fact, however, this opinion is so far wide of the truth, that I can only understand it as an

[1] Roberts Bartholow. Camp Fevers, being chap. 2 of the Medical Volume of the Memoirs of the U. S. Sanitary Commission. New York, 1867, p. 193 et seq.

[2] Op. cit., p. 126. [3] Op. cit., p. 214. [4] Op. cit., p. 196.

illustration of the extent to which one may be led astray by the eagerness of controversy. It is not necessary to leave the volume in which Bartholow's paper is printed to find evidence to contradict him. You will find such evidence in the paper by Dr. Sandford B. Hunt,[1] which constitutes the third chapter of the volume; and in the first chapter of the volume, by Dr. Bartholow himself,[2] he makes a series of statements which fully justify my views. Thus, he affirms that the amount of aliment furnished to the various armies was too often "determined by the transportation available for bringing it forward, and by the so-called military necessity;" and that "the armies operating in the interior region were more affected by deficiencies in commissariat supplies than those on the Atlantic coast," of which fact he gives several striking examples. He explicitly states that "the diet was not sufficiently varied." "Antiscorbutics came to be furnished after the first year of the war, but the chief antiscorbutic—the potato—was practically unavailable, from the difficulty of transporting and preserving it."

Is it wonderful that, in this connection, Dr. Bartholow, adopting the very term he criticizes when used by me, should have felt compelled to write: "A scorbutic taint was to be observed in troops who had served in the South for a considerable period;" and, further on, that "an impoverished state of the blood, due to defective alimentation, undoubtedly existed to a large extent. It exhibited itself in various forms, but especially in increasing the fatality of diseases and in impressing an adynamic character on those of mild and tractable forms." Still further: "The camp fever of the army was essentially typhoid. It was modified by various accidental and specific causes. We have just alluded to one of the specific modifying causes—malaria. The most important of the others was scorbutus."

It would occupy too much time for me to attempt to bring forward even a small part of the evidence on which my belief of the wide-spread existence of a scorbutic taint among our troops during the late war rests. My own observations and opinions have been corroborated by those of numerous capable medical officers. As for actual pronounced scurvy, so fully developed that it could be recognized by the average regimental surgeon, 30,714 such cases, not of the scorbutic taint, but of "SCURVY," were officially reported among the white troops during the war, and 16,217 among the colored troops.[3]

The other critic to whom I desire to refer is Dr. Jerome Cochran, of

[1] Op. cit., p. 64. [2] Op. cit., pp. 16–19.

[3] The ratio of these cases to strength greatly increased during the latter part of the war, and attained formidable proportions among the troops sent to Texas during the year following the war. The following ratios are computed from the tables published in the first volume of the Medical History of the War:—

Ratio of Cases of Scurvy per 1000 *of mean strength.*

WHITE TROOPS.	
Year ending June 30, 1862	4.7
" " " " 1863	12.6
" " " " 1864	9.6
" " " " 1865	22.4
" " " " 1866	28.4
COLORED TROOPS.	
Year ending June 30, 1864	66.5
" " " " 1865	65.0
" " " " 1866	141.6

Mobile, whose objections I find in the Transactions of the Medical Association of the State of Alabama for 1875.[1] This gentleman's service as a surgeon in the Confederate Army inclines me to regard his somewhat grotesquely presented criticism with a respect I could not have felt had it proceeded from a less reputable source. Singularly enough his objections precisely contradict the objections of Bartholow; so that I might readily call upon either gentleman as a useful witness to contradict the asseverations of the other. Bartholow will see nothing in the continued fevers of the war but the typhoid element; Cochran will see nothing in the fevers around Mobile but the malarial element.

"During the last six months," he writes, "several cases of protracted fever, primarily of malarial origin, but assuming in their course certain typhoid symptoms, have been related to the Society under the name of typho-malarial fever." He objects to this term and the theory which it implies. He thinks the fevers in question are purely malarial. "The malarial mother is easily found, the fruitful mother of many children, but for the typhoid father I have looked in vain through all the streets and alleys, in all the wards and suburbs of the city;" and again: "I can only continue to say that if we have typhoid fever here, I have never seen it."

Now, the very same volume in which Dr. Cochran publishes this, contains a tabular statement of the deaths in Mobile during the year 1874. Among these I find three from intermittent fever, twelve from remittent fever, seven from congestive fever, one from typho-malarial fever, six from yellow fever, one from hemorrhagic-malarial fever, and five from typhoid fever.[2] Dr. Cochran himself tells us in the course of his remarks that his antagonists among the Mobile physicians declare the existence in that town of "a continued fever with diarrhœa, dry tongue, frequent delirium, a rose rash, running a persistent course of three weeks or more, and defying all treatment to arrest its progress;" but he will not admit that this fever is typhoid. He does not bring forward any dissections in proof of his views; indeed, he does not appear to have made a single autopsy in any of the cases in dispute. He bases his opinion entirely on *a priori* considerations deduced from his belief in the incompatibility of the idiopathic fevers. He proclaims that "there can be no doubt whatever of the truth of John Hunter's general doctrine, that no two of them can exist in the same part of the body at the same time." I can only express my belief that if Dr. Cochran had spent a part of the time which he has employed in criticizing my views, in making, with his fellow-practitioners, some autopsies on the cases of fever, which he tells us they persist in calling typho-malarial and typhoid, he would have arrived at results quite at variance with the opinions he has expressed.

And now, one word before I close, as to the question of nomenclature. Is it convenient to bestow a single term, as I have done, upon the whole brood of hybrid forms resulting from the simultaneous action of malaria and of the causes of typhoid fever; or, is it best to use several designations according as the one or the other of the two elements predominates? We might give the cases in which the typhoid element predominates the name miasmatic-typhoid fever, suggested by Levick,[3]

[1] Jerome Cochran. Note B. Typho-malarial Fever. Trans. of the Med. Association of the State of Alabama, 28th Session, 1875. Montgomery, Ala., 1875, p. 337.

[2] Op. cit., p. 314.

[3] Op. cit. supra; also a lecture by the same author, Miasmatic Typhoid Fever. Med. and Surg. Reporter, June 21, 1862, p. 283.

and call those in which the malarial element predominates typhoid-miasmatic fever. Such a double nomenclature we have already seen was suggested by Hermann Schmidt. We might go still further, and apply special names, in accordance as the malarial element showed itself, by giving to the early stages of the case an intermittent or remittent type. I do not think this is at all necessary. I think a single term which shall include all the hybrids quite sufficient; but I shall not quarrel with any one who wishes to make further subdivisions.

If we agree to represent all these hybrid forms by a single appellation, is the designation Typho-malarial the best for the purpose? Would it be an improvement to adopt the term "entero-miasmatic," suggested as a substitute by Dr. George B. Wood?[1] I confess to a preference for the term I have suggested. It is easy enough to pronounce, and seems to me to express its meaning very well; but I attach far less importance to the employment of the name which I have suggested than I do to the recognition of the compound forms of fever which I intended to represent by it. The name is, after all, a mere matter of choice. But if I have rightly presented the subject, a just appreciation of the hybrid forms which I have urged on your attention to-day is a matter of grave practical importance. Not merely as a question of Military Medicine, though most important in that connection, for I take it that whenever again hereafter an army recruited in a comparatively non-malarial region shall campaign on a malarial soil, these hybrid forms will appear once more in epidemic proportions; but meanwhile, I suppose, in sporadic or endemic-wise, we shall continue to have these cases to deal with in civil practice in all the miasmatic regions of our Middle and Southern States, and their right comprehension is, therefore, a question of serious moment to every American physician engaged in practice in such localities.

Discussion on Dr. Woodward's Paper.

After the reading of the preceding paper, Dr. Roberts Bartholow, of Cincinnati, said:—I have listened very attentively to the paper just read, and as it refers to some criticisms of mine, I feel called upon to reply. I have studied Dr. Woodward's writings, and, with many other physicians of the United States, have labored under the impression that he had attempted to erect the Typho-malarial fever into a distinct type of disease. Now he recalls, denies, and repudiates what he has formerly published. In the paper which I had the honor to contribute to the volume issued by the Sanitary Commission, and to which allusion has been made, I simply stated that there were distinct cases of simple typhoid and of remittent fever in the army of the United States. As a practitioner in the Ohio Valley, I have seen cases of fever in some of which the malarial, and in others of which the typhoid element predominated. The paper just read throws no new light on the subject. The form of disease referred to has been long since known. I must repudiate the idea that the statements in my paper were made in an acrimonious spirit. When eminent medical men publish their views, the most obscure member of the profession has a right to express a difference of opinion, and should not be stigmatized as acrimonious simply because he utters his opinions in a determined and fearless manner.

Dr. Woodward said:—I wish simply to say that Dr. Bartholow undertook to write a history of the fevers of the Civil War for the Sanitary Com-

[1] Op. cit., vol. i. p. 377.

mission. He criticized my views, as I thought, in an acrimonious spirit, and I resolved at the time to reply, but have not till the present occasion had a convenient opportunity. If after reading my paper, Dr. Bartholow still thinks that I have misrepresented his criticism, I will offer him an apology for having done so.

Dr. N. S. Davis, of Chicago, said:—I had not supposed that the term "typho-malarial" was intended to indicate any specific form of fever, and am surprised that the author of the paper seems to combat the idea that it should be so received. I supposed that it meant simply the intermingling of the causes of two distinct forms of fever, in such a way that they influenced the human system at one and the same time. This phenomenon of intermingling has been familiar to me ever since I took up my residence in Chicago, in 1849. Then it was almost universally believed that our fevers were of a malarial character; very few recognized typhoid fever as such. The locality was highly malarious. The population was about 30,000, and there was not a foot of sewerage. The supply of water was drawn from superficial wells, and the prevalence of intermittent and remittent fevers was very distinct. Ten or twelve years later, when sewerage had extended, and a supply of lake water had been supplied, the intermingling was observed. Cases of fever at their onset were regarded as malarial, but, not yielding to the influence of quinia, were ultimately recognized as of a typhoid character. As time passed on, the typhoid element predominated, and we now find no difficulty in recognizing the intermingling of types.

Dr. W. Scott, of Cleveland, Ohio, said:—I rise to bear testimony to some of the facts set forth in Dr. Woodward's paper. Physicians of thirty years' standing in the Ohio Valley, and especially in the southern portion of the State, remember the time when this complex condition was unknown. Our experience is that the typhoid element is not affected by the use of quinia. When I have recognized this mixed form of disease, I have given quinia in sufficient doses to destroy the intermittent character of the affection, when the fever persists in the continued form. In 1864 I was in Nashville, and observed many cases of scurvy among the soldiers in the Nashville hospitals.

Dr. Wm. Pepper, of Philadelphia, said:—At the time I first read Dr. Woodward's publications on the subject of typhoid and malarial fevers, they made a clear impression on my mind; and I think his views as now expressed are the same with slight modifications as to the anatomical relations of these two affections. I confess, however, to some hesitation as to the propriety of employing a special term to distinguish a disease which is not itself specific. A great deal of confusion has resulted from the use of such terms; and I have found many who regard typho-malarial fever as wanting the specific characters of typhoid fever, and as, therefore, not requiring the same care as the ordinary uncomplicated form of the disease. We meet with cases of typho-malarial fever in this city, and I have myself become very familiar with it. It is found itself, however, to present so many forms and varieties, partly depending on the relative proportion in which the typhoid and the malarial elements are combined, as to render it very difficult to give a clinical definition of it. Moreover, I have not found that the symptoms which are usually given as indicating the coexistence of the two poisons, are as constant and reliable as appears to be thought by many, and as they certainly must have been in the army cases upon which Dr. Woodward founded his classical memoir. Thus, for instance, it is true that in the malarial form of typhoid fever an initial chill and an early rise in temperature are more common than in the uncomplicated form. But there are so many irregularities in the mode of onset and course of typhoid fever, apart from any complication, as to render this of uncertain value. And in this connection I would add that careful study of the irregular and abortive forms of typhoid fever has convinced me that the fixed rules for the temperature curve in this disease adopted by many authors, must be very considerably modified. What I have said of the initial chill and the fever-curve, I might say

of the kind of tongue thought to be characteristic; of the relative frequency of eruption, diarrhœa, epistaxis, etc., in the two forms of the disease. We are not in the habit of erecting into special types of disease the cases of other affections which are complicated with malaria—as, for instance, pneumonia, dysentery, etc., and, although in the case of typhoid fever this complication is certainly more frequent than in any other affection, it appears doubtful to me whether it would not be better to include typho-malarial fever under the general head of typhoid fever, and to merely designate it as the "miasmatic form" of that disease. Still, there is a feeling among physicians that the use of the term "typho-malarial" is convenient, and it is perhaps desirable that for the present at least it should be recognized.

The Secretary read the following remarks contributed by Dr. J. A. Estlander, of Finland:—At certain periods, malarial fever is very common along the southern coast of Finland; at other periods it disappears altogether. During the last years of the decade 1850–60, it reigned over the whole coast, but from 1860–68 it disappeared so completely that not one single case was to be met with at the hospital. From the last-named year until the present time, it has again plagued this part of the country very severely, but seems now to be fast decreasing. This periodicity seems to depend on the atmospheric pressure, for when during our short summer the average range of the barometer is high, the water-level is low, and the bottom of the sea, in the numberless small creeks and bays penetrating the shores of the Gulf of Finland (where, by the way, no tide is perceptible), lies uncovered and exposed to the sun. When, on the contrary, the mean barometer is low, all is covered with water, and the summer is rainy and cold, but free from malaria. The abdominal form of typhoid fever may be called endemic in my country, for cases of that fever occur every year and at every season, although sometimes with more, sometimes with less, intensity and frequency. At such periods, when the malarial fever is very intense, we often see cases exactly like those so well described by Dr. Woodward. These cases most frequently appear in spring and autumn, and particularly in the early part of the last-named season, to wit, the month of August, for such, in this land of short summers, this month is designated. For this reason, this fever is in my country commonly called "Augusti-feber." Dr. Woodward has named this form of fever "Typho-malarial," to define it as a hybrid of the typhoid and the malarial fevers, and I gladly accept this name and its signification. It is a well-known fact that during a period when the malarial constitution is predominant, many diseases combine in a curious manner with this fever, as for instance diarrhœa and bronchial catarrh, particularly in children, and therefore such a concurrent action of separate intoxications, as the name "Typho-malarial" implies, has many analogies in pathology.

On motion of Dr. Woodward, seconded by Dr. Pepper, the following was adopted as expressing the opinion of the Section:—"Typho-malarial fever is not a specific or distinct type of disease, but the term may be conveniently applied to the compound forms of fever which result from the combined influence of the causes of the malarious fevers and of typhoid fever."

ARE DIPHTHERITIC AND PSEUDO-MEMBRANOUS CROUP IDENTICAL OR DISTINCT AFFECTIONS?

BY

J. LEWIS SMITH, M.D.,

PHYSICIAN TO THE INFANT HOSPITAL, NEW YORK, ETC.

The term Pseudo-membranous Croup, Membranous Croup, or, for brevity, Croup, is applied to a sporadic inflammation of the larynx, which is accompanied by the formation of a pseudo-membrane upon the laryngeal surface. It is attended by no symptoms. except such as are referable to the local disease, and it destroys life by the mechanical effect of the exudation. Croup is universal; Steiner says, "Croup extends over the whole world, but strikingly diminishes in frequency, according to A. Hirsch, as we pass from the higher latitudes to the tropics." Therefore nearly every physician in general practice meets cases from time to time. My present purpose is to consider the relation of this malady to an inflammation of the same parts, which is accompanied by a similar exudation and with similar local symptoms, but which we know to be a form of, or a manifestation of, a contagious and epidemic disease, namely, diphtheria.

There are two theories regarding the relation to each other of croup and diphtheritic laryngitis. The *first* is that they are entirely distinct, that the one is a simple, non-specific inflammation, not capable of reproducing itself, while the other is specific and contagious; that, therefore, they sustain to each other, as one of our writers has well said, a similar relation to that which exists between ordinary metritis and the metritis of puerperal fever, having sufficient clinical differences to justify our regarding them as distinct maladies. The *second* theory is thus enunciated by one of its foremost advocates (Steiner): "The attempt to distinguish croup and diphtheria as two entirely distinct diseases has been unsuccessful, both from an anatomical and a clinical standpoint; indeed there are many good reasons for supposing that these two affections are only varieties and modifications of one and the same process, which, in consequence of special influences and collateral causes, as yet imperfectly understood, makes its appearance at one time as croup, at another as diphtheria, now in a sporadic form, now as a wide-spread epidemic, now as a primary, now again as a secondary affection."

The attempt to elucidate the nature of croup, and determine its relation to diphtheritic laryngitis, is attended by unusual difficulty for one who makes his observations in a locality where diphtheria prevails, as is the case with most of us who reside upon the Atlantic coast. The difficulty alluded to arises from the impossibility of making a clear and certain diagnosis of croup, where diphtheria is endemic. Has not every physician in such a locality, now and then, believed, that he was treating a case of croup, such as he had, perhaps, observed in former years, even adhering to the diagnosis till the death of the patient, when the subsequent history of contagiousness has taught him that, after all, the case was one of diphtheria? There is no symptom or anatomical fact observed at the

bedside which will enable the physician to say that the case is croup, and not laryngeal diphtheria. Absence of a pseudo-membrane upon the fauces does not, as some seem to think, establish the diagnosis of croup, for I have treated undoubted cases of diphtheritic laryngitis, ending fatally, in which there was not only no diphtheritic pellicle upon the surface of the pharynx, but only a mild degree of catarrhal pharyngitis. Nor is the absence of glandular swelling under the ears certain proof that the laryngitis is croupous, instead of diphtheritic, for, although it is true that considerable tumefaction is a sign of diphtheria, yet this swelling is sometimes absent in cases which are clearly diphtheritic.

For correct and reliable facts in regard to croup I have found it necessary to consult medical literature, and to depend upon my own recollection, and that of the older physicians of New York, as to cases which occurred prior to 1857, at which time diphtheria became established as an epidemic and endemic of the city, and upon the observations of intelligent physicians in localities where diphtheria does not prevail. I am under obligation to physicians who have thus aided me. The relation of croup to diphtheritic laryngitis may be conveniently considered under the following headings—

I. *Croup a local malady ; diphtheritic laryngitis the expression or manifestation of a general disease.*—The late Dr. Hillier, of London, a close observer of diseases, inclined to the belief that croup was a constitutional malady, but the following facts strongly indicate its local nature. Its causes, as we shall see, are the same or similar to those of the ordinary inflammations, which are admitted to be strictly local. There is no evidence, from the symptoms, of any systemic infection or blood disease, and recovery immediately follows relief of the local malady. The depression which attends cases of diphtheria is lacking. If croup were a general disease, there should be, it seems to me, in some cases at least, anæmia, poor appetite, weakness, etc., indicative of the blood change, for a longer or shorter time after the removal of the laryngeal obstruction and abatement of the inflammation.

As evidence, also, that croup is not a constitutional disease, is the fact that the inflammation is almost invariably—I have heard of no exceptional case—limited to a single tract of the mucous membrane. It is the uniform recollection of the older physicians of New York with whom I have conversed in reference to this matter, that they never observed a case of croup, before the advent of diphtheria, which was attended by membranous exudation upon other surfaces than that of the pharynx and air passages. Were there systemic infection, or blood poisoning, in croup, we should expect that, in some instances at least, the characteristic inflammation and exudation would occur in other localities also, as in diphtheria, especially since nearly every mucous membrane in the system is susceptible of croupous inflammation. Another fact indicative of the local nature of croup, is its tolerance of depressing remedies, as we shall see hereafter. Constitutional diseases having inflammatory lesions, badly tolerate such agents. From clinical and anatomical facts like the above, the profession has long regarded croup as a local malady, and I can see nothing in the most recent investigations regarding its nature to shake the belief in this opinion.

How is it with diphtheritic laryngitis, as this inflammation ordinarily occurs? Is it local, occurring independently of blood changes and produced by the lodgment of the diphtheritic virus upon the laryngeal sur-

face; or is it the result of the presence of the diphtheritic virus in the blood, so that it sustains the same relation to the general disease, that the pharyngitis of scarlet fever and the bronchitis of measles do to those diseases? The latter theory, namely that the laryngitis and other inflammations of diphtheria are the result and outward manifestation of an infected or poisoned system, was generally accepted by the profession of this country and Europe during the last twenty-five years, until the publication of the bacterian theory. This theory (according to which it is claimed that a microscopic organism, which is the cause or specific principle of diphtheria, has been found making its way from the surface, on which it has lodged or been received from the air, through the tissues into the circulation) has shaken the belief of many in the constitutional nature of diphtheria, and they incline to the other view, which certain experiments seem to support, that diphtheria in ordinary cases begins locally, and that blood poisoning may or may not result, but that if it does, it is secondary.

It is a matter of great importance—an importance transcending that of almost any other subject relating to the pathology of this dreadful scourge—that we should ascertain clearly and certainly which of the two prevailing theories is true, since the theory influences practice. Is the opinion correct, that the primary event is the entrance of the poison into the blood; or the other opinion, that the poison is received upon an exposed surface, where it excites inflammation, and that the blood either escapes contamination, or receives the poison by absorption or penetration from the inflamed surface?

Experiments on the lower animals have thus far failed to demonstrate the primary nature of diphtheria, as it occurs in the human race. Among the most recent experiments which have a bearing upon this subject, are those of Dr. Rajewsky, performed with the approval and at the instance of Prof. Von Recklinghausen. Rajewsky poisoned the blood of rabbits by injecting diphtheritic matter into it, and then produced catarrhal inflammation of the intestinal mucous membrane by injecting a weak solution of ammonia into the intestine, when the interesting result followed, that the catarrhal became a diphtheritic inflammation. Obviously in these experiments diphtheria was primarily constitutional. The diphtheritic inflammation was developed from within—from the poisoned state of the blood. But in another class of experiments, he first produced catarrhal inflammation of the intestines in the same manner as before, and then injected diphtheritic matter into the intestine. The result was the same as regards the production of diphtheritic inflammation upon the intestinal surface, for upon the inflamed portion, to which the poison was applied, the characteristic diphtheritic pellicle appeared. It may be inferred, that in this class of experiments the primary action was local, but may not absorption of the poison have preceded the local disease, as is now believed to be the case in syphilitic inoculations?[1] (Bumstead.)

The fact that diphtheritic inflammations ordinarily occur upon those surfaces which are most exposed to currents of air, and upon which any deleterious substance floating in the air would be most likely to lodge, has been supposed to lend support to the theory that diphtheria is at first localized in these exposed parts. But if these inflammations were ordinarily produced by the direct contact of the poison received from the air,

[1] Lond. Med. Times and Gaz., Dec. 11, 1875.

coryza ought, it seems to me, to be the primary diphtheritic inflammation in a large proportion of cases; whereas it is not ordinarily primary, and in many cases does not occur at all. The fact is that the diphtheritic virus, in whatever way its reception occurs—whether in the ordinary manner, or through a wound of the skin—appears to be especially attracted to the fauces and contiguous parts, or to find in them the seat of its greatest activity, so that even if the disease is received through a distant part of the system, pharyngitis is apt to occur. Thus Hillier relates the case of an eminent surgeon who, performing tracheotomy on a child supposed to have croup, punctured his thumb. The puncture was painful, and on the following day a pustule occupied its site. This was opened and poulticed. "A day or two later, on removing the epidermis, the subjacent cutis was found in the condition of a peculiar dark slough; there was an entire absence of suppuration, and excessive pain. This was followed in six days by a diphtheritic deposit on the tonsils. The wound on the thumb was long in healing." A month later, diphtheritic paralysis occurred.[1] In cases like the above, if they are correctly interpreted, and the poison is received through the skin, it is evident that the inflammations on the exposed mucous surfaces are not produced by the direct deposit of the virus, but that they result from the blood poisoning. And the important and interesting fact appears, that, in cases thus contracted by inoculation, diphtheria is constitutional, before the pharyngeal or laryngeal inflammation occurs.

But if we could obtain no farther light in reference to the primary nature of diphtheria than what is afforded by experiments on animals and accidental inoculations in man, we would probably never know, when called at the commencement of a case contracted in the usual manner, whether we had to treat a merely local affection, or a constitutional disease with local manifestations. We must fall back to the wider field of clinical experience for help to an understanding of this matter. The following facts, taken collectively, afford, in my opinion, strong corroboration of the theory that there is primary systemic infection in diphtheria, as it is commonly contracted:—

(1) *The long incubative stage in certain cases.*—Although the incubation of diphtheria is ordinarily from two to five days, it is sometimes an entire week, as in the following examples: In April, 1876, a little girl died of malignant diphtheria in West 41st Street, New York. Her sister, aged one year, remained with her from April 14 to 17, when she was removed to a distant part of the city, and placed in a family where there was no sickness, and had been no diphtheria. On the night of April 24, seven days after her removal, this infant was observed to be feverish, and on the following day, when I was called to examine her, the characteristic diphtheritic patch had begun to form over the left tonsil. In April, 1875, two sisters, aged seven and five years, resided with their parents, in a boarding-house, in West 22d Street, New York. A playmate in the same house had symptoms which were supposed to be due to a cold, but which were diphtheritic, when one night severe laryngitis occurred, and ended fatally the next day. The physician who had been summoned diagnosticated diphtheria, and the two sisters were immediately removed to a hotel. But seven days subsequently, diphtheria commenced in the older child. The younger was at once removed to a distant part of the same hotel, but on the sixth or

[1] Hillier on Diseases of Children.

seventh day subsequent she also became affected with a fatal form of the disease.

Now according to the doctrine that diphtheria is at first local, and that the inflammations result from the irritating effect of the virus which lodges upon the mucous membrane, this virus must remain inactive a week upon the surface where it is received. Such inactivity in a poison of unusual energy and malignity would be very improbable. But we have sufficient explanation of the long incubation, if, in whatever way the poison is received, it first enters the blood, and the inflammations occur consecutively to the blood-changes. It is a law in pathology that those specific diseases which have an incubation of several days, are constitutional.

(2) Another fact, which indicates primary blood poisoning in diphtheria, is observed in certain cases, namely, the *occurrence of severe constitutional symptoms for a longer or shorter time, perhaps for half a day, before the appearance of the usual inflammation.* Thus a girl of five years, having malignant diphtheria, whom I saw in consultation, was carefully examined on the first day of her sickness by the attending physician, and although he closely inspected the fauces, there was no appearance which indicated the nature of the malady till the subsequent day. In such cases, a sufficient number of which I have observed, there is apt to be complaint of soreness of the throat, or difficulty in swallowing, almost from the beginning of the general symptoms; but the pain and tenderness seem to be in the deeper tissues of the neck, and the fact that redness of the mucous surface does not appear till some hours subsequently, is evidence that the inflammation is developed from within, and not from the irritating effect of the poison upon the surface.

Again, treatment of the inflammations by the most reliable and efficient antiseptics and disinfectants which we possess, commenced at the earliest possible moment and repeated at short intervals, does not prevent the occurrence of indubitable symptoms of blood poisoning in cases of a severe type. Thus I have treated every portion of the inflamed surface, as far as it was accessible, every second or third hour, with carbolic acid and other disinfectants, almost from the very commencement of diphtheria, and so thoroughly that any vegetable or animal poison, with which the remedies had come in contact, would probably have been destroyed, or rendered inert, and yet, except in mild cases, symptoms of diphtheritic blood poisoning have occurred, and as early and uniformly as if less energetic local measures had been employed. While, therefore, I do not fail to recommend local treatment as calculated to prevent septic poisoning, and relieve the inflammations, I have lost confidence in it as a means of preventing the entrance of the diphtheritic poison into the blood. Its powerlessness to prevent contamination of the blood by the diphtheritic virus is an additional evidence that this contamination occurs independently of the local disease, and probably precedes it.

(3) *The quick succumbing of the system in certain malignant cases* is evidently due to diphtheritic toxæmia. We sometimes observe a fatal result on the second, third, or fourth day, without any dyspnœa, or sufficient laryngitis to compromise life. Cases of this kind, terminating fatally even in the first day, have been reported. The system is suddenly overpowered by the poison, struck down, as it were, by the profound blood change, while the inflammations are still in their incipiency.

(4) Important evidence of the constitutional nature of diphtheria is afforded also by the *state of the kidneys*. No internal organs are so often

affected in diphtheria as the kidneys, and on account of their location and anatomical relation, it is evident that the poison first passes through the system before it reaches them. Any clinical or anatomical fact, therefore, which indicates that the diphtheritic virus has reached and affected the kidneys, affords proof that it has penetrated the system, and poisoned the blood. Now the occurrence of albumen, with granular or hyaline casts, in the urine, in cases unattended by dyspnœa, affords proof of nephritis, caused by the action of the poison on the kidneys. Dr. West, from observations made in London, believes that albuminuria is commonly present in diphtheria, but the frequency of its occurrence varies in different epidemics, according to the severity of the type.

During the latter part of 1875, and in 1876, prior to Aug. 1, I endeavored to obtain and examine the urine in every case of idiopathic diphtheria, having a clear diagnosis, which came under my notice, both in family practice and in the institutions with which I have an official connection. Ordinarily, during the first week of a case, I found that the urine deposited urates on cooling, and that the nitric acid test showed a large relative quantity of urea, but I suspect that this was due to a somewhat diminished quantity of urine. But the occurrence of albumen was of chief interest, and the results of the examinations as regards the presence or absence of this, are recorded in the accompanying table. In most of the cases the urine was examined several times in the course of the disease, and, if albumen were present, a microscopic examination was also made. In nearly all the specimens which contained albumen—all but three or four—casts, usually granular, but now and then hyaline, and sometimes both kinds in the same specimens, were observed. In those cases of albuminuria which recovered, there were comparatively few casts, or none. If the albumen were abundant, and casts plentiful, the case was usually fatal, though not perhaps till after the lapse of three or four weeks, when death occurred with symptoms of exhaustion, paralysis, or feeble heart-action, sometimes with œdema of lungs supervening suddenly, and, probably, formation of heart clots. The albuminuria, unlike that of scarlet fever, seldom occurred except in the grave cases; and in the majority of instances it did not appear till near the close of the first week, or in the second, and, in a few instances, not till a later period. Although the albuminuria of diphtheria is much more grave than that of scarlet fever, it has in my practice been attended by much less serous effusion or dropsy, often by none which was appreciable. The urine, although containing a large quantity of albumen, often had nearly the normal appearance, instead of the smoky or hazy color so common in the albuminous urine of scarlet fever.

I. *Cases attended with the usual membranous exudation upon the fauces, with or without coryza, and without laryngitis or with only catarrhal laryngitis; fifty-eight cases.*

	Died.	Recovered.	Result not stated.	Total.
With albuminuria . . .	13	5	1	19
Without albuminuria . . .	4	27	1	32
State of urine not recorded .	3	4	..	7

II. *Cases attended with membranous laryngitis as the predominant inflammation; nineteen cases.*

	Died.	Recovered.		Total.
With albuminuria . . .	4	1	..	5
Without albuminuria . . .	2	4	..	6
State of urine not recorded .	7	1	..	8

The mortality of the cases embraced in the above table was probably larger than the average in New York practice, for several of them were seen in consultation, and their type was severe. Those in which the state of the urine could not be ascertained, were usually in children so young or so near death that it was impossible to obtain sufficient urine for examination. It is not improbable, also, that, occasionally, in cases in which it is stated that there was no albumen in the urine, it may have been present at a more advanced stage of the disease, or on days when the examination was not made; but, as stated above, there were usually several examinations of the urine made during the progress of each case.

Sir John Rose Cormack, of Paris, in a series of interesting and useful papers relating to diphtheria, published in the Edinburgh Medical Journal during the present year, states that albuminuria, and of course the nephritis on which it depends, sometimes begin as early as the first day. My observations confirm this statement, as in the following cases:—

Case I.—L. McD., aged three years, was first visited by me on Feb. 29, 1876. I learnt from the parents that she had been feverish during the preceding forty-eight hours, and her urine very scanty. A moment's examination was sufficient to show that the case was one of malignant diphtheria, for the fauces were already nearly covered by the diphtheritic pellicle, the temperature was 103¼°, and the pulse 140. The skin was hot and dry, and there was moderate swelling under the ears, and a muco-purulent discharge from the nostrils. On account of the scantiness of the urine, the amount not exceeding ℥iv–v daily, it was impossible to obtain sufficient for examination till the following day. It was then found to have a specific gravity of 1032, to contain a deposit of urates and hyaline and granular casts, a diminished amount of urea, and a large quantity of albumen. It can hardly be doubted from the scantiness of the urine, and the large amount of albumen found when the urine was first examined, that albuminuria had been present on the first day.

Case II.—The following was a similar case: K., aged four years, living in West 36th Street, was visited by me in consultation on Jan. 29, 1875. Her sickness had also continued forty-eight hours; her fauces were swollen, and covered with the diphtheritic pellicle, which was dark and offensive; respiration guttural; pulse 120; temp. 101°; she had a free discharge from each nostril; urine scanty, its specific gravity 1030; it contained a small amount of albumen, with casts, and a large amount of urates, with no apparent diminution of the urea. Death occurred on the fourth day.

In such severe cases, in which albumen and casts are found in the urine at the first visit of the physician, there can be little doubt that the nephritis begins nearly or quite as early as the pharyngitis, and therefore, since poisoning of the blood must antedate the renal disease, diphtheria is in these cases very early, probably from the occurrence of the first symptoms, a constitutional malady.

Again there are cases, though rare—only one I can recall to mind during the last two years in my practice—in which the external manifestations of diphtheria are very mild, even insignificant, and quickly cured, but in which the kidneys are severely affected. The occurrence of such cases is best explained on the supposition that the first departure from the state of health is in the blood, and that the blood change gives rise to the inflammation of the mucous membrane externally, and of the kidneys internally, rather than upon the supposition that the transient and insignificant inflammation of the mucous membrane is the first event in the series of morbid changes, and that this inflammation leads to poisoning of the blood, and the establishment of a much more severe

and protracted inflammation in the kidneys. The following is the case alluded to:—

Case III.—The house, 229 West 19th Street, New York, is an old wooden structure, and the family, which has occupied it during the last five years, has been three times visited by diphtheria, the first case, that of the oldest child, proving fatal. In February, 1876, one of the children had diphtheria in a moderately severe form. He recovered, and, after my visits had been discontinued, his sister, aged six years, who had had scarlet fever when eighteen months old, became feverish and complained of her throat. No rash appeared on her skin, and there was apparently no coryza. Inspection of the fauces by the parents revealed a small diphtheritic patch over each tonsil. Although diphtheria was so frightful a malady to this family from their past experience, the case seemed so mild that the parents treated it without medical attendance, by the remedies which had been employed for the boy. A mixture of carbolic acid, subsulphate of iron, and glycerine, was applied to the fauces every third hour, sufficiently often, apparently, to destroy all bacteria or other vegetable or animal organisms with which it might have come in contact, and within two or three days the inflammation of the throat seemed to the parents to be cured. Nevertheless, with this insignificant inflammation of the fauces, so quickly subdued, and with no other apparent inflammation of the mucous surfaces, there was severe internal disease going on as the result of the general infection. The child did not regain her former appetite; she had increasing pallor, although able to play about the house; and, finally, in the third week, when I was called to see her, slight œdema of the face and limbs was observed. Her urine, which was scanty, was found to contain pus and blood corpuscles, albumen, and granular casts, and nearly two months elapsed before, under treatment, it became normal, and her health was restored.

One more clinical fact which I have often observed, may be cited in support of the opinion that diphtheria is primarily constitutional, and that the inflammations are secondary, and dependent on the blood poisoning. It is this: When the inflammations of the mucous surfaces have apparently ceased, or only slight catarrhal inflammation remains, and the apartment in which the patient has been treated has been thoroughly disinfected, and local treatment discontinued, we are perhaps surprised to observe the reappearance of the diphtheritic pellicle, though less in extent and with less severe symptoms than at first. It is highly improbable that diphtheria has been contracted a second time. The rational explanation is that the reappearance of the inflammation is due to the fact that the blood is still infected; that, as when syphilitic eruptions reappear, it is not yet fully purified of its noxious elements. I have seen this return of the diphtheritic pellicle even in mild cases in which there was no other evidence of general disease. If the second occurrence of the inflammation is due to the poisoned state of the blood, is it not probable that the first inflammation is also thus produced?

I have perhaps occupied too much space in attempting to show, what indeed many already believe, that croup is simply a local malady, while diphtheritic laryngitis is one of the inflammations which result from a general malady. But within the last three or four years, the old doctrine that diphtheria is local in its commencement, and is therefore, in at least many instances, amenable to early local treatment, has been revived, and so promoted by the advocates of the bacterian system, that it already influences the treatment in many quarters. There are physicians, as I have had opportunity to observe, who attach little importance to constitutional measures, if they are called early to a case, and who rely almost entirely on local treatment for the relief of the patient.

But with a correct understanding of the nature of diphtheria, I am convinced that we must continue to regard constitutional remedies as of prime importance.

The evidence is therefore strong that, while croup is primarily and constantly local, diphtheria, as it ordinarily occurs, is a general disease from its commencement, and that the laryngitis and other inflammations result from and manifest the blood poisoning.

II. *Anatomical characters identical in kind, as regards the state of the larynx, but differing in degree or intensity.*—Most of the microscopic examinations of the pseudo-membrane, made during the last twenty years in this country and Great Britain, in cases of supposed croup, must be received with hesitation and distrust, on account of the great difficulty to which allusion has already been made, of making a clear diagnosis in localities where diphtheria prevails. For although diphtheritic laryngitis can often be diagnosticated from croup, the reverse, namely, the diagnosis of croup from diphtheritic laryngitis, is attended by such difficulty, and is so uncertain, that we can obtain, as already stated, reliable statistics of croup only from those observers who reside in localities in which diphtheria does not occur.

Fortunately, for our purpose, there are or have been localities where pathologists have been able to observe the clinical and histological characters of croup, free from the embarrassment to which I have alluded. Thirty years ago the great treatise of Carl Rokitansky, on Pathological Anatomy, appeared, a vast repository of pathological facts, derived from thirty thousand dissections. No one has ever had better opportunities than he, for studying the anatomy of diseases, and no opinion has carried, and still carries, greater weight than his, in all subjects relating to morbid anatomy which do not involve the use of the microscope. I am informed that even up to the present time, in Vienna, where Rokitansky's observations were made, diphtheria is almost unknown, and in his treatise he scarcely makes any allusion to it, so little did he know of it. We may therefore confidently believe that what this renowned observer states in relation to croup, relates to the genuine disease.

Says Rokitansky, "The croupy process occurs on all mucous membranes, and sometimes extends over a very wide tract. The mucous membrane of the respiratory organs shows an especial tendency to it, and we meet accordingly with laryngeal croup, tracheal croup, bronchial croup, and croupy pneumonia." He says, also, which I wish to emphasize, "Neither during nor after the croupy process does the mucous membrane suffer any material injury to its texture; the speedy production of mucus and epithelium prevents any further organization of the plastic exudation, ... and it never enters into an organic connection with the mucous membrane."[1] Dr. Heitzmann, now of New York, who was assistant to Rokitansky till 1874, informs me that diphtheria had not appeared in Vienna up to the time when he left that city, and that Rokitansky still held the same views in regard to the anatomical characters of croup.

Prof. Rindfleisch, of Bonn, says of the pseudo-membrane of croup: " . . . it spontaneously separates, since it is loosened by a moderate production of pus, first at the edges, and then raised from its base. . . Rarely is a secondary enlargement of the pseudo-membrane perceived,

[1] Pathological Anatomy, vol. iii., page 56, Sydenham Society's Translation.

never a reproduction at the same spot." "The boundary between the mucous and the false membrane is naturally very much obliterated by this gradual transition of the cells of both sides, although it never becomes quite indiscernible. It, however, is undoubtedly evident, that the pseudo-membrane is produced by a secretion of young elements at the surface of the irritated mucous membrane, and by their gradual induration, sclerosis, vitreous tumefaction, or by whatever other name we wish to call the degeneration." "The pseudo-membrane is of a peculiarly stratified structure, since upon a layer of cells, at tolerably equal distances, there always follows a layer of fibrin, and this sequence is repeated from one to ten times, according to the thickness of the membrane. Whether I am correct, in directly calling those second layers fibrin, must of course remain a question. I do it upon the first impression which its configuration makes, and with the reservation that therewith I always have in mind only a fluid albuminate, but indurated by the transudation into the air."[1]

Mr. Jabez Hogg, President of the Medical Microscopical Society of London, in 1873, said, as reported in the Monthly Microscopical Journal for that year: "A portion of a croupous cast, examined under a power of 350 diameters, is seen to consist of pavement and cylindrical, or columnar epithelium, and a transparent albuminous substance, entangling the scattered contents of epithelial cells, molecular matter, fat and mucous corpuscles, and a few foreign bodies, involved in a homogeneous matrix. When stained by a weak solution of ammoniacal carmine, or aniline dye, and carefully spread out with needles, the columnar epithelium retains its cilia, each cell being filled with clear protoplasmic and nucleated contents. It is therefore highly probable that these cells are not long retained, but are rather thrown off soon after their formation."

It will be observed that these authorities, from whom I have quoted (and most microscopists and pathologists agree with them), state that the pseudo-membrane of croup consists, mainly, of altered epithelial cells, held together by an albuminate which exists either in the form of layers, or a network. In the interstices, or meshes of this network, we find, in addition to the epithelial cells, granular matter, with embryonic and pus cells. The mucous membrane underneath is more or less denuded of its epithelium, is thickened and softened, and of a bright red color from active congestion of its vessels; or the redness is diminished and its color paler, if the inflammation has to a considerable extent abated.

Does croup produce any other anatomical changes, in addition to those which have been described above, and which are located in or along the air passages? Apart from those blood changes which occur in all inflammations, I believe that there are no other uniform lesions, except such as result from the passive congestion of organs which is ordinarily present in advanced cases, and which is proportionate in degree to the amount of laryngeal, or laryngo-tracheal obstruction. When the dyspnœa becomes so great that lividity of the lips and tips of fingers occurs, a correspondingly severe and dangerous congestion of the internal organs results. Hence œdema of the lungs and albuminuria may supervene in the last hours of croup. I am convinced from my own observations, and from the nature of this malady, that those who believe that they have observed other lesions of croup, as enlarged and altered spleen, enlarged

[1] Pathological Histology, translated by Kloman and Miles, §§ 364, 365, 367.

Peyerian and solitary glands, etc., have observed merely accidental lesions, or have mistaken diphtheritic laryngitis for croup.

Let us now consider the lesions of diphtheritic laryngitis. In order to determine their precise nature, I have obtained the help of skilful microscopists in New York. Dr. Satterthwaite kindly consented to make microscopic examinations of the organs in the first and second cases. The specimens were placed in a solution of bichromate of potassium immediately after their removal from the bodies. The following case occurred in my private practice:—

Case IV.—H——, aged four years, and two brothers S., who lived directly opposite in the same street in New York, were daily playmates. On January 27, 1876, H—— became feverish and complained of sore throat, and four days subsequently died of malignant diphtheria. This case was carefully examined by me in consultation, and minute records of it preserved. Before it terminated, the two brothers S. became affected with diphtheritic laryngitis. The younger brother, aged three years, was for a time in a very critical state from the dyspnœa, but recovered in about one week. The older brother, aged six years, died, having the following history: On January 29, two days after the commencement of diphtheria in his playmate, H——, he vomited and became feverish, and his voice became hoarse. These symptoms continuing, I was asked to visit him on Feb. 2. His respiration at this time was harsh, and audible in the adjoining room, and the cough croupy; pulse 96; temperature in axilla 100°; he takes considerable nutriment, and sits quietly, or walks about the room; fauces red, and slightly swollen, but without any diphtheritic exudation upon their surface; has slight glandular swelling underneath the ears; the urine contains no albumen, and the nitric acid test shows no excess of urea. The constant inhalation of the spray of lime-water is recommended, with the use of tonics. Feb. 4. Pulse 96, temperature 99°; breathes with much difficulty at times, but there is still no pseudo-membrane upon the fauces; has expectorated since the last record two thick pieces of pseudo-membrane, each about one inch in length, apparently from the larynx; specific gravity of urine 1022; it contains a deposit of urates, but no albumen; urea apparently somewhat in excess of the normal quantity. Feb. 5. Pulse 92; temperature $101\frac{3}{4}$°; has a small diphtheritic patch, not more than three lines in diameter, over the left tonsil. Feb. 6. The pellicle upon the tonsils has disappeared; the urine for the first time albuminous, thirty-six hours before death; its specific gravity 1024; temperature 103°; dyspnœa great; pulse about 120. Death occurred on Feb. 7.

Sectio Cadaveris, 19 hours after death; body spare, but not emaciated; rigor mortis present; has post-mortem extravasation of blood along the back, and a thin blood-stained fluid escapes from the mouth; two or three drachms of transparent liquid in the pericardial sac; a large yellowish-white clot fills the right ventricle, and is prolonged into the pulmonary artery; the right auricle also contains a large clot, soft and dark in its centre, but firmer and of a whiter color externally; left ventricle contains a few soft dark clots, with a little fluid blood; left auricle partly filled with blood of a tarry appearance; tonsils not enlarged, but soft, and a yellowish diffluent secretion lies in the depressions on their surface; subcutaneous glands of the neck slightly enlarged, one being somewhat larger than a filbert; under surface of epiglottis, and entire surface of larynx, covered by a firmly adherent pseudo-membrane which entirely conceals from view the vocal cords and the sinuses of Morgagni; the pseudo-membrane is continued over the surface of the trachea, being less adherent than in the larynx, and, near the bifurcation, it floats freely; it does not extend into the bronchus or bronchial tubes of the left lung, and this lung is normal. In the right lung the pseudo-membrane extends as far as the bronchial tubes of the third order; the upper lobe of the right lung is in the second stage of pneumonia, its cut surface being rough and granular, and

liquid escaping from it on pressure; the right, middle, and lower lobes are congested, and in the lower lobe is a single hepatized nodule; those portions of the bronchial tubes which are not covered by the false membrane exhibit the appearance of catarrhal bronchitis. The liver is large, and not fatty; spleen small, moderately firm, and contracted (this is noteworthy, as the spleen has been found large and soft in diphtheria); kidneys congested and swollen, and a stellate appearance of the vessels under their capsules; surface of both small and large intestines congested.

Microscopic Examination.—Red corpuscles of the blood well-preserved, some of them round, others crenated, and all granular; large masses of transparent material, containing red corpuscles, floated in the blood. The rod and chain forms of bacteria were observed in the blood, but not in greater number than are often seen in other blood the same number of hours after death. (A few grains of chloral had been added to this specimen of blood immediately after its removal.) Substance of heart apparently normal, showing no fatty degeneration, nor infiltration; no bacteria can be recognized in the substance of the heart. *Kidneys:* Right kidney examined; Malpighian bodies congested, and extravasations of blood throughout this organ; tubal epithelium granular; increase of connective tissue in points near periphery of kidney, showing interstitial nephritis, but no increase observed in this tissue in other parts of the organ; no bacteria that could be certainly recognized as such in the kidney. *Spleen:* Multitudes of granules in scrapings from the cut surface of this organ, many of them so small as to be with difficulty recognized with a magnifying power of over 600 diameters; some of them gave the appearance of the usual forms of bacteria.

Larynx: Thickness of false membrane which covered the entire surface of this organ varied from $\frac{1}{100}$ to $\frac{1}{25}$ of an inch; thickness of mucous membrane about $\frac{1}{50}$ of an inch; epithelial border of mucous membrane could be traced inwards $\frac{1}{200}$ to $\frac{1}{100}$ of an inch, where it became indistinct, merging into the other tissues which were more or less infiltrated with embryonic cells and blood. The false membrane consisted of a network of a homogeneous material, most of the meshes being empty, but those nearest the epithelial layer containing more or fewer epithelial cells. The boundary line between the false membrane and the mucous surface could not be distinguished by the microscope in many of the sections, the network of the pseudo-membrane extending into the mucous membrane. But in other places the line of separation could be distinguished, and here and there the pseudo-membrane and mucous surface were separated by collections of embryonic cells. The lymph follicles and racemose glands were apparently normal; mucous surface infiltrated with granular matter and red blood corpuscles; cylindrical epithelial cells, some of them with cilia, were distinctly visible both along the free border, and in the under surface of the pseudo-membrane. *Trachea:* The false membrane measures from about $\frac{1}{100}$ to $\frac{1}{30}$ of an inch in thickness; the mucous membrane $\frac{1}{50}$ of an inch, and its epithelial layer $\frac{1}{120}$ of an inch; the epithelial cells are much more distinctly visible than in the larynx, and the line of separation of the adventitious layer and the mucous surface is everywhere distinctly seen under the microscope; the false membrane has the same general appearance as in the larynx, but the mucous membrane is in a better preserved state than that of the larynx; it is nevertheless infiltrated with granular matter, plastic matter, and red blood corpuscles; lymph follicles and racemose glands apparently normal; in the trachea, as in the larynx, a large number of embryonic or lymphoid cells—most of them no doubt becoming pus cells—lay between the false membrane and the mucous surface.

Case V.—A second case, having the following history, occurred in the Catholic Foundling Asylum in New York. George, aged two years and seven months, was under treatment for a second attack of measles, the eruption appearing on March 23, 1876. On March 24, the pulse was 136 and temperature $104\frac{1}{2}°$. The fauces presented a deep-red appearance, indicating severe

pharyngitis, but without any membranous exudation. March 25. Pulse 140; temperature $103\frac{1}{4}°$; the rubeolar eruption is very thick over the entire surface. The Sister who has charge of the ward, noticing unusual offensiveness of the breath, has inspected the fauces and found on them the diphtheritic pellicle. March 26. Cough becoming croupy, and voice hoarse; pulse 152, temperature $105\frac{1}{4}°$. From this date the dyspnœa progressively increased, and death occurred on March 30.

Sectio Cadaveris.—A considerable part of the interior of the larynx is coated with the diphtheritic pseudo-membrane, which is firmly attached to the mucous surface; it extends without interruption over the larynx, and perhaps over one-third to one-half of the tracheal surface. It is not attached to this surface, but hangs over it like a curtain, suspended from its attachment in the larynx. Further down in the air passages there is the usual catarrhal inflammation of the mucous surface.

Microscopic Examination.—Larynx: The false membrane is found to consist of a network, apparently fibrinous; in places, in the larynx, it is raised from the mucous membrane by an accumulation of embryonic or lymphoid cells underneath; in other places it is adherent to the mucous membrane, but with a line of attachment which can be distinctly made out with the microscope; while in other places still the network extends down into the mucous membrane, and no distinct line of separation can be seen. In the upper, or exposed portion of the false membrane, no embryonic or lymphoid corpuscles are observed, but they are abundant in the deeper portion, and they infiltrate the whole mucous membrane extensively; upon the mucous surface, wherever the pseudo-membrane is detached, these corpuscles are abundant; in parts of the false membrane they fill so completely the interstices of the network that epithelial cells can scarcely be distinguished within them; in places, in the sections examined, the epithelium seemed to be wholly replaced by granular matter; in general, the border line between the diphtheritic membrane and the mucous surface is marked by a somewhat denser exudation of the albuminate—a fibrinous appearing material—than is seen in the false membrane generally; the bloodvessels in the mucous membrane of the larynx are numerous, and distended with blood. *Trachea:* The epithelium, consisting of from two to three layers, is seen to be intact wherever it is observed; the surface of the epithelium is covered with minute markings, probably the cilia in contraction; the pseudo-membrane is not seen to be reticulated as in the larynx, perhaps from the contractions which had occurred in it; it appeared granular and fibrous, and contained but few corpuscles. *Lungs:* A portion of one lung was found hepatized, and the alveoli of this portion contained pus cells, epithelial cells, blood, and a fibrinous appearing material (croupous pneumonia). *Kidneys:* The changes observed in these organs were those of tubal nephritis; the tubes were highly granular, both in the pyramids and cortex; no increase in the interstitial connective tissue was noticed; in places the tubes were not granular. The muscular tissue of the *heart* seemed normal.

In the following case, in which the larynx was not involved, Dr. Carl Heitzmann, late of Vienna, made a microscopic examination of the kidneys, in order to determine more exactly the histological changes which these organs undergo in diphtheria, and how these changes contrast with the lesions which may result from simple passive congestion, such as is present in the kidneys in fatal cases of croup.

Case VI.—J——, aged four years, an inmate of the Catholic Foundling Asylum, began to have sore-throat on March 4, 1876. The fauces were red and somewhat swollen, but without any membranous exudation, and the diphtheritic nature of the disease was not at first suspected. My attention was first called to this case on March 11, on account of almost total suppression of urine. The fauces were still injected, and somewhat swollen from catarrhal inflammation; there was a copious muco-purulent discharge from the nostrils;

pulse 148. March 13. Pulse 144; temperature $101\frac{1}{4}°$; urine still nearly suppressed, though one drachm of infusion of digitalis is administered every fourth hour, and bromide of potassium, four grains, every second or third hour, for the restlessness. Dr. Reid, in using the catheter, observed a diphtheritic patch on the vulva; there is moderate tumefaction under the ears; the patient vomits often during the last days; she has livid spots, from extravasation, under the skin; and vision is much impaired, if not lost; it is impossible to obtain any urine for examination. Death occurred without convulsions on March 15.

Microscopic Examination of the Kidneys. (By Dr. Heitzmann.)—The tubuli contorti of the first and second order of the cortical substance of the kidney almost all enlarged; their epithelium swollen in many places to such a degree that no calibre of the tubules can be seen; the epithelium richly provided with coarse granules, the enlarged living matter; the original cement substance missing; instead of this, new transparent lines formed within the protoplasm, indicating the earliest stage of catarrhal inflammation, with partition and new formation of epithelial elements; the same changes, though in a less marked degree, observable in the epithelium of the straight ducts of the pyramidal substance, while the flat epithelial bodies of the narrow ducts appear almost unchanged. The connective tissue between the ducts and the enlarged glomeruli is somewhat increased in size, and it contains newly-formed nuclei in moderate number, with enlarged bloodvessels, some of which are much distended with blood-corpuscles; no fatty degeneration in kidneys. In a few places, accumulations of dark granules occur within the ducts and their epithelium. These granules, not being united with each other by threads, nor staining with carmine, are considered to be micrococci, such as occur in any decomposing animal tissue. Whether they were present during the life of the patient, or were due to early cadaveric putrefaction (which is common after death from diphtheria), is uncertain. But since I have seen micrococci and bacteria in the fresh urine of children suffering from diphtheria, I would not deny the possibility of the occurrence of micrococci in the uriniferous tubules during life; nay, even, they may produce the inflammatory process in a way still unknown to us. In the case under consideration no trace of casts was found within the tubules, so that the inflammatory process doubtless was not a croupous one, but a relatively slight process, termed catarrhal or interstitial nephritis.

The above microscopic examinations in cases of diphtheritic laryngitis and nephritis, correspond with those made by other observers. The following facts in reference to the histological characters of croup and diphtheritic laryngitis, we wish especially to call attention to:—

(1) The croupous and diphtheritic pseudo-membranes consist alike of altered or degenerated epithelial cells, mingled with embryonic, or growing pus cells and matured pus cells, all held together by an albuminate, probably fibrin, which exuding in a liquid state from the mucous membrane underneath, surrounds the cellular masses like mortar around the stones in a wall, and hardens on exposure to the air. The consistence and toughness, therefore, of the adventitious layer, are largely due to the albuminate. The exact chemical character of the albuminate, and the chemical changes which the epithelial cells, of which the pseudo-membrane is composed, have undergone, have not been clearly ascertained, but so far neither the microscope nor chemical tests show any qualitative differences which hold good as a means of distinguishing the false membrane of croup from that of diphtheria. Supposed differences, observed by some, have not been noticed by others with other specimens. The tests of organic chemistry are not sufficiently delicate for the detection of any uniform difference in the nature of the two exudations, if any difference exist, which seems improbable.

(2) The laryngitis of croup, as compared with that of diphtheria, is

more superficial. Most inflammations of mucous surfaces, which are due to sudden changes of temperature or exposure to currents of air, as simple coryza or bronchitis, are more superficial than specific inflammations, or inflammations due to poisonous principles, acting locally, or through the blood. Croupous laryngitis is no exception. It produces less infiltration in the mucous membrane and submucous tissues, and consequently less thickening, and less exudation of the albuminate from the deeper vessels, than occurs in diphtheritic laryngitis.

(3) Croup is a transient inflammation. It commonly begins to abate when the exudation which relieves the congested vessels has occurred. Hence the statement of Rindfleisch, that the pseudo-membrane when detached by suppuration underneath, is never reproduced. The cause of croup acts only for a brief period, and therefore the effect soon begins to abate, if there is no fresh exposure. This transitory nature of croupous inflammation contrasts with the greater persistence and depth of the laryngitis of diphtheria. It is probably not absolutely true that the pseudo-membrane of croup is never reproduced. Nevertheless, the distinction holds good, that there is much less tendency to its reproduction, and less tenacity of the inflammation in croup than in diphtheritic laryngitis. There seems to be a marked similarity, not only in the nature and relations of the false membrane, but in the progress of the inflammation, in croupous phlegmasia, as it occurs in the different divisions of the respiratory tract, that occurring in the minute bronchial tubes and in the alveoli of the lungs, in the common disease croupous pneumonia, being best understood on account of its frequency. As in this disease the exudative stage soon ceases, and resolution commences with the decline of the inflammation, so in laryngeal or laryngo-tracheal croup the greatest danger is from the first exudation, and if the first pseudo-membrane can be removed by treatment there is a fair prospect of a favorable termination. In this fact lies one of the chief points of contrast in the anatomy of croup and diphtheritic laryngitis, for from the persistence of the diphtheritic inflammation, and longer continuance of the exudative stage, the diphtheritic pseudo-membrane, if expelled, will probably reform, as in one of the cases related above, and reform more than once.

(4) The pseudo-membrane of croup is more or less closely adherent to the mucous surface underneath, but most microscopists who have examined specimens removed from the bodies of those who have died of undoubted croup, agree that it does not penetrate it. The superficial character of the inflammation, and the fact that the exudation occurs from the superficial vessels, afford explanation of this fact. In diphtheritic tracheitis, we have found, in the specimens examined above, that the pseudo-membrane also lay upon the mucous surface without penetrating it; and in one of the cases, in which pneumonia had occurred, the fibrinous exudation also lay free within the alveoli of the lungs. But in the larynx, the albuminate, which formed the network of the pseudo-membrane, penetrated the mucous membrane in places so that the line of demarcation was extinguished; while in other places a distinct line of separation of the exudation and mucous membrane was observed under the microscope, though the two surfaces were in close contact; while in other places still, the exudation was elevated above the mucous membrane by the secretion of embryonic or pus cells underneath This intimate relation of the false membrane to the mucous surface w long since pointed out by Virchow, and has been confirmed by m microscopists since. But it is to be remembered that exceptional es

have been reported, in which the pseudo-membrane lay entirely upon the mucous surface without penetrating it. This admits of explanation without impairing the accuracy and truthfulness of the general statement in reference to the intimate relation of the diphtheritic pellicle with the surface of the larynx. For the adventitious layer is detached by cell formation or suppuration underneath, so that in most specimens, as in those described above, there are places in which the detachment has already occurred. If then the stage has arrived in which there is more abundant and general suppuration, the detachment of the false membrane will be in a corresponding degree more extensive. To this intimate relation of the exudation with the mucous membrane in diphtheria, is due the fact that points and patches of ulceration are so commonly observed in this membrane when the diphtheritic layer is detached. Perhaps cases occur, which from their commencement are exceptions to the above statement in regard to the relation of the pseudo-membranes to the laryngeal surface in croup and diphtheria. Perhaps there are cases of mild diphtheritic laryngitis in which the exudation lies entirely upon the surface, as it lay on the tracheal surface in the cases narrated above, but there can, I think, be little doubt that in a series of cases of the laryngitis of croup and diphtheria, the anatomical difference, as stated above, would commonly be observed in the two diseases.

(5) While the lesions of croup, apart from those of the respiratory apparatus and pharynx, result from the passive congestion which corresponds in degree with the amount of dyspnœa, there are or may be in diphtheritic laryngitis additional lesions which result from the blood poisoning, as hemorrhages upon the free surface or in the tissues of organs, sometimes fatty degeneration of the cardiac muscular fibres, and frequently desquamative or interstitial nephritis. The last case related above shows that the renal affection may be an interstitial nephritis, with almost total suppression of urine, occurring without desquamative nephritis, and therefore without the formation of casts, while in other cases the inflammation is largely desquamative, as shown by the presence of a large number of casts. This frequent occurrence of severe nephritis, interstitial and desquamative, contrasts strongly with the milder form of renal affection which occurs in croup. In croup there is passive congestion, with perhaps albuminuria, if the dyspnœa be severe, but I can find no evidence that there is any liability to those dangerous forms of nephritis with suppression or scantiness of urine, which are so common in diphtheritic laryngitis as well as in diphtheria when manifested by other forms of external inflammation. The following case may, I think, be appropriately related in this connection, as showing the blood changes and renal disease to which I have alluded, as common in diphtheritic laryngitis, but as absent or very exceptional in croup. It is true that the case was one of diphtheritic catarrhal laryngitis, but there is obviously no essential difference between dipththeritic membranous and catarrhal inflammations, and, wherever the former occurs, we commonly find at the same time a border or zone of the latter coexisting with it. This case is also interesting to the practitioner, as showing the inefficiency of the antiseptic treatment to prevent the blood changes of diphtheria:—

Case VII.—M., aged four years, inmate of the Catholic Foundling Asylum, New York, began to be sick May 6, 1876; was languid and feverish, temperature 104°, had redness of fauces and an exudation over each tonsil, no coryza; vening, temperature 103°. May 7. Pulse 120; temperature 100°. May 8. lse and temperature as yesterday; urine scanty; no albuminuria, and no dis-

charge from nostrils; the membrane extends from the sides of the throat to the roof the mouth; sp. gr. of urine 1021, urine contains no albumen, no excess of urea, and no deposit of urates. May 10. Pulse 140; has considerable œdema of fauces, and breathing guttural in sleep; vomited once since yesterday; the urine contains for the first time a moderate amount of albumen, with hyaline casts; sp. gr. 1018, acid; no urea deposited on adding nitric acid; that alarming symptom in diphtheria, epistaxis, has occurred to-day. The records which were written daily till death, which occurred on the 14th, show a gradual increase of albumen with hyaline casts in the urine, increasing scantiness of urine, so that on the 13th not more than half an ounce was passed in twelve hours; temperature not rising above $100\frac{1}{4}°$, nor pulse above 108; poor appetite, occasional vomiting, and epistaxis. Death occurred from feebleness and blood-poisoning, notwithstanding that, from the first day, three grains of salicylic acid were given the first hour, two grains of quinine the second hour, and tincture of iron and chlorate of potassa the third hour, these doses having been continued night and day in alternation; with the application of carbolic acid and subsulphate of iron to the fauces, three times daily; with nutritious diet, and the moderate use of stimulants. There were no symptoms referable to the larynx, unless a slight cough.

Sectio Cadaveris.—Mucous membrane of larynx, trachea, and bronchial tubes intensely and uniformly injected, but without any membranous exudation; lungs fully inflated, as if from commencing vesicular emphysema, and pale in front; numerous extravasations of blood in the substance of the lungs and other organs; the hemorrhages in and under the mucous membrane of stomach so abundant that the gastric surface presented a mottled appearance like the skin in measles.

Microscopic Examination. (By Dr. SATTERTHWAITE.)—The mucous membrane of the larynx and trachea was hyperæmic, but was otherwise apparently normal; muscular tissue of heart normal; spleen soft, but not appreciably enlarged. The scrapings of the cut surface of this organ contained red blood-corpuscles; bodies from two to five times the size of the blood-corpuscles, holding in their interior oil drops and fine granules, and having a yellowish-red color; granular lymphoid corpuscles, and granular débris. The walls of the stomach were congested, but without any noticeable exudation upon the surface; the extravasations of blood, described above, were found to be chiefly in the submucous tissue. In some places the gastric tubes were bare, but in other places covered with amorphous matter; but whether the covering substance was altered epithelium or diphtheritic exudation was not determined. The epithelium covering the more exposed portions of the tubes was in many places not distinct, while that covering the deeper portions of the tubes was clearly defined; at the pylorus, upon the valve, the mucous membrane was deficient; those portions of the true peptic glands lying below the tubes were normal. The mucous membrane in the lower part of the ileum was congested. Peyer's patches, and the solitary glands, both in the ileum and large intestines, were prominent, and surrounded by halos or rings of inflammation. Both the cortical and pyramidal tubes of the kidneys contained granular epithelium.

In croup the blood certainly undergoes anatomical changes as in other inflammations, and becomes overcharged with carbonic acid when the respiration is embarrassed; but I am not able to find records of any case of undoubted croup, or of croup occurring in a locality where diphtheria does not prevail, in which such profound destructive changes occurred in the blood, as were present in the above case of diphtheritic catarrhal laryngitis, and as are common in diphtheria whether accompanied by laryngeal or other form of inflammation. I must, therefore, conclude that croup and diphtheritic membranous laryngitis possess such local and general anatomical differences as justify our regarding them as essentially distinct.

III. *Clinical Facts which indicate the Duality of these two Diseases.*—The season of the year and the weather influence the occurrence of croup. Exposure to currents of air and sudden changes of temperature are its common causes. In tropical climates, croup is less frequent than in the moist and cold climates of higher latitudes. In localities swept by cold winds, or liable to sudden variations in the atmospheric heat, croup, as well as pseudo-croup and bronchitis, are common, for these diseases have a common cause. The following example, which I recall to mind, may be cited as showing how croup is commonly produced. A little girl, at a time, and in a locality in which no diphtheria was occurring, had an ordinary attack of measles. As she was beginning to convalesce, though still having some cough, she sat for some time in an open window through which the wind was blowing. On the following night membranous croup commenced, ending fatally in about two days.

The cause of diphtheritic laryngitis is different. It is a contagious principle which poisons the blood, and produces certain inflammations quite independently of atmospheric conditions. Exposure to winds and sudden thermal changes play a very subordinate part in causing diphtheritic laryngitis. They may sometimes act as predisposing causes, by irritating or inflaming the mucous membrane, for clinical experience and experiments on animals show that in a system affected by diphtheria, the specific inflammation is most apt to appear on such surfaces as are irritated or inflamed. Only in this respect can diphtheritic laryngitis be said to have the same cause as croup. In cases which I have observed, I have rarely had occasion to suspect that the patient had taken cold. I have frequently seen the laryngitis occur when there had been every precaution to prevent taking cold, and the proportion of cases of diphtheritic laryngitis has been, I think, nearly as large in warm and equable portions of the year, as in seasons of cold and changeable weather.

Again, croup very seldom occurs under the age of eighteen months, nor over the age of fifteen or sixteen years. Physicians in New York, whose practice extended over a number of years before diphtheria commenced, tell me that they never saw croup after the fifteenth or sixteenth year. Now diphtheria and diphtheritic laryngitis are not rare between the ages of six months and two years. I have seen minute white points over the tonsils, in an infant of six weeks, whose brother was dying of diphtheritic laryngitis, and there are a few cases on record of new-born infants affected with diphtheria,[1] though it is the universal experience that very young infants are less liable to diphtheria than those who are older.

Every physician, again, who has witnessed a severe epidemic of diphtheria, or who has practised where diphtheria is endemic, knows how frequently it occurs in youth, and in the first years of manhood. The statistics of New York epidemics furnish a considerable number of cases which were fatal from diphtheritic laryingitis between the ages of twenty and forty years. There is, therefore, a marked difference as regards the limits of the age in which diphtheritic laryngitis and croup occur.

But the strongest argument in favor of the duality of croup and diphtheritic laryngitis, and one which, to my mind, is conclusive, is derived from the fact that the one is non-contagious and the other highly contagious. Physicians of New York, who saw cases of croup prior to

[1] See Bost. Med. and Surg. Journ., March 11, 1875; also Contributions to the Pathology and Therapeutics of Diphtheria, by A. Jacobi, M.D., New York, page 26.

the time when diphtheria occurred, and country physicians, in localities where diphtheria has not yet prevailed, have informed me, without an exception, that they never saw any evidences of the contagiousness of croup. Would not intelligent physicians, whose united practice in localities not yet visited by diphtheria gives more than a century of observation, be able to record a single instance of the contagiousness of croup, if it possessed in any degree a contagious principle? Contrast this fact with the fearful contagiousness of diphtheritic laryngitis. Now I hold that if two maladies are identical in every other respect, but one is contagious and the other non-contagious, it will be necessary to give them different places in nosology. Contagiousness, although it be a new property assumed by an old and well-known malady, so transforms its nature that it becomes to all intents and purposes new and distinct.

The following is also an interesting fact, as showing an important difference between croup and diphtheritic laryngitis. In New York City, statistics of the mortality have been preserved since 1804, and in the long period from 1804 to 1850, inclusive, no case of diphtheria, or none recognized as such, occurred within the city limits. Now, during this time, croup was not infrequent, the yearly number of deaths from it never falling below 60, which was the number in 1817; nor exceeding 356, which was the number in 1850; the average yearly number being 148.2, and the total number for the forty-seven years being 6964. Physicians of New York, whose practice extended over the latter part of this period, state that they occasionally, at rare intervals, saw cases during this time which resembled diphtheritic pharyngitis, but which went by the name of malignant angina, or malignant sore throat. One of the prominent surgeons of New York lost a child from this sore throat about the year 1833.

Rokitansky tells us that all the mucous surfaces are liable to croupous inflammation; and were these pseudo-membranous pharyngeal, or pseudo-membranous laryngeal, inflammations of the first half of the present century, croupous; or were they the inflammations of diphtheria, which still lingered in the city in a modified form since the great epidemic of the eighteenth century, which Colden and Bard described? Certain facts may be stated which indicate the croupous, and not diphtheritic, nature of these inflammations: first, the absence of all history of contagiousness; and, secondly, the fact that the laryngitis was so much more frequent and fatal than the pharyngitis. The statistics of diphtheria, the world over, show, as every one knows, an excess of cases of diphtheritic pharyngitis over the cases of diphtheritic laryngitis; while the number of fatal cases of diphtheritic pharyngitis and diphtheritic laryngitis is either about equal, or as two to one. From the year 1804 to 1850, there were in New York 6964 deaths from membranous croup, while the deaths from all other forms of inflammation of the throat, including the membranous, for they were all grouped together, numbered only 1387, or about one-fifth of the number of deaths from croup. Now does not the wide difference between the frequency and mortality of these inflammations during the half century, when there was no diphtheria to modify diseases, and of diphtheritic pharyngitis and laryngitis of the present time, indicate a difference in the nature of the inflammations in the two periods?

Let us state the argument in different terms. If the croup of New York, in the first half of the present century, were a modified diphtheritic laryngitis, can any one tell us why membranous pharyngitis, during

the same period, was comparatively rare, and fatal membranous pharyngitis so very rare that the majority of physicians did not meet with a case in years of practice ; when in true diphtheria, the world over, membranous pharyngitis is the most frequent diphtheritic inflammation in fatal cases, as well as in those which have a favorable issue?

Writers have also very properly called attention to the fact, as showing an essential difference between croup and diphtheritic laryngitis, that the former is seldom followed by paralysis, whereas paralysis is common in those who recover from diphtheria, whatever the form of inflammation from which they have suffered.

The results of treatment also indicate a difference in the nature of croup and diphtheritic laryngitis. In croup, emetics, even those of a depressing nature, are tolerated. There is rarely any serious depression, except in advanced cases of croup, from the occasional use, in emetic doses, of ipecacuanha or tartrate of antimony and potassium, so as to expel muco-pus from the bronchial tubes, or any portion of the pseudomembrane which may be detached. In diphtheritic laryngitis, the employment of these agents, under any circumstances, is hazardous, and the profession generally, observing their ill effects, have abandoned the use of all emetics in diphtheria, even those which are least depressing. I recollect that, in New York City, soon after diphtheria began to be prevalent, physicians were sometimes astonished at the rapid sinking of patients with diphtheritic laryngitis, whom they had treated as they had previously treated cases of croup. Thus a girl, aged about ten years, with moderate dyspnœa, but whose case did not seem to be immediately dangerous, took an emetic of "hive syrup," by the physician's advice, and sank so rapidly that she died in an hour or two later. More recently I saw a child of three years, whose dyspnœa did not seem to be extreme, suddenly sink into fatal prostration, under doses of tartrate of antimony and potassium which the physician in attendance had ordered.

While in croup death results from the obstructed respiration, and consequent imperfect oxygenation of the blood, there is the same source of danger in diphtheritic laryngitis, but also the additional danger which results from blood poisoning and structural changes in important organs, as the heart and kidneys. Hence, fatal as is croup, diphtheritic laryngitis involves greater danger, and is less amenable to treatment. Moreover, as we have seen above, in ordinary cases, there are probably greater infiltration of the mucous membrane and longer continuance of the exudative process in diphtheritic laryngitis than in croup, and consequently greater liability to reproduction of the pseudo-membrane. It will be recollected that in one of the cases related above, the patient expectorated two pieces of pseudo-membrane, of considerable size, three days before death, but that the denuded places had been so completely refilled that the surface from which the detachment had occurred was not apparent at the autopsy. If the views now expressed in reference to the relative duration of the exudative period in croup and diphtheritic laryngitis be correct, and I see no reason to doubt them, it is evident that the expulsion of any considerable portion of pseudo-membrane affords much stronger hope of a favorable termination in a case of croup, than in one of diphtheritic laryngitis.

Statistics of tracheotomy for membranous laryngitis which was supposed to be chiefly croup, derived from the surgical practice in New York City some years since, before diphtheria became fully established

as an endemic, gave a mortality of about 77 per cent.,[1] whereas the result of this operation at the present time, in cases which are believed to be chiefly diphtheritic, is much less favorable. A prominent surgeon of New York informs me that in about twenty consecutive cases of tracheotomy for diphtheritic laryngitis, he has saved only one; and another surgeon has saved only one in thirteen cases; while another still, who has probably performed tracheotomy oftener than any other practitioner in New York, has saved only two in about forty operations during the last four years, and has reason to doubt the genuineness of the disease in one of the two which recovered. My data are insufficient for positive statement, but I incline to the belief, from cases which have been reported to me and from conversations with the surgeons, that it is necessary, in cases which do well, to retain the canula longer on an average after the operation for diphtheritic laryngitis, than after that for croup. We would expect this, if there is greater infiltration, and a more protracted exudative stage, in the former than in the latter disease; and although I have known the canula to be safely removed, in one case of diphtheritic laryngitis, at the close of the third day, I think it is oftener necessary to retain it the greater part of a month, or even longer. Wishing to be understood as not committing myself to this last statement in regard to the length of time during which it is necessary to maintain the artificial opening in tracheotomy for croup and diphtheritic laryngitis, for my records are too few for a positive assertion, nevertheless the results of medical and surgical treatment indicate, in my opinion, a wide difference in the two forms of inflammation.

Those who believe in the essential oneness of croup and diphtheritic laryngitis, believe, as far as I can learn, that the croup of former times has been greatly modified to become the diphtheritic laryngitis of the present day. But how far can a malady undergo modifications and yet preserve its identity? Invest a local disease with a specific principle, or call into activity a specific principle which has hitherto lain dormant in it, rendering it a constitutional and contagious disease, and its nature is so transformed that it becomes to all intents and purposes a new malady. It is not dressing up an old disease in a new garb, but it is changing its very essence or nature into something new and distinct.

In this connection an interesting fact is suggested. Those who practise in localities where diphtheria is endemic, often observe other forms of inflammation becoming diphtheritic. The pharyngitis of scarlet fever, when the primary disease has continued a few days, is often complicated by, or transformed into, a diphtheritic inflammation; and I have seen diphtheria thus commencing spread as an independent malady. A similar change in the character of the inflammation is also common in measles, especially during severe epidemics of diphtheria. And not infrequently an inflammation of the air-passages, apparently at first catarrhal, and probably so diagnosticated by the physician, presents in a few days the grave characters of the specific inflammation of diphtheria. It is, therefore, in my opinion an open question, whether the exudative inflammation of croup may not afford a favorable nidus for the reception and development of the diphtheritic virus, so that a case commencing as croup may become one of diphtheria. Perhaps this may explain the apparent fact that croup is less frequent in localities where diphtheria is established, than in former times.

[1] See the author's Treatise on the Diseases of Children.

Discussion on Dr. J. Lewis Smith's Paper.

After the reading of the preceding paper, Dr. William Pepper, of Philadelphia, said :—It seems to me that the recognition of a radical difference between diseases which possess strong points of resemblance and analogy, is a very delicate matter, and that the arguments in favor of such separation should be very clear and unanswerable. In the present case we have to deal with forms of disease characterized by the production of a peculiar pseudo-membrane upon the surface affected. Although there are many grades of severity, and therefore many differences in degree, between the lesions in different cases of croup and diphtheria, I am confident that no essential difference exists either in the microscopical or chemical characters of the pseudo-membrane in the two forms of disease, nor in its relation to the subjacent surface. This form of exudation is so peculiar and distinctive that a strong presumption would seem to exist in favor of the relationship of two affections in both of which it is developed. In considering the arguments against this relationship, which have been so fully and ably presented by Dr. Smith, I am unable to feel that they are convincing. We must not think of diphtheria only in its grave epidemic form, but also in the mild, sporadic form which so frequently occurs. I meet very frequently with isolated cases of undoubted pharyngeal diphtheria (for I would carefully exclude all cases of herpetic follicular angina with pseudo-membranous formation of a different kind), in which the constitutional symptoms are not very asthenic, albuminuria is usually absent, glandular swelling is not very great, there is no evidence of profound constitutional infection, and paralysis rarely follows. In such cases there is by no means the very marked difference from the general symptoms of membranous croup that has been assumed to exist.

It has frequently been my experience also, as I have stated elsewhere in connection with Dr. J. Forsyth Meigs, to find that cases which had been regarded as idiopathic croup, had really been preceded by slight faucial diphtheritic deposits, and were consequently undoubtedly diphtheritic in nature. It is true that the pseudo-membrane may first occur in the larynx in some cases, but I should be glad to see more careful and numerous records of such cases, where no pellicular formation in nares or fauces was present at any period. In different epidemics, and at different times, the proportion of cases of diphtheria in which the deposit occurs in the larynx is very variable. At times very few cases of croup occur; at others, the number is large; in a few epidemics, the larynx has been, as a rule, the first and only part affected. In these instances the attendant constitutional symptoms, and the rate of mortality, have been such as are found in grave epidemics of naso-pharyngeal diphtheria. Last winter I attended a case of membranous croup with highly sthenic general symptoms, in the eldest of three children. No faucial deposit was detected, but there had been nasal catarrh for a few days before the laryngeal symptoms appeared. The child died from suffocation, the operation of tracheotomy having been refused. In every respect this case resembled so-called idiopathic membranous croup; yet, before the child's death, the youngest sister sickened with a dangerous naso-pharyngeal diphtheria, from which she recovered without laryngeal implication. I might quote other cases of similar character.

Nor do I think the results of treatment afford a reliable basis of separation. We cannot regard diphtheria, any more than pneumonia, as though it had a constant and uniform type. There are cases of the one, just as of the other, which will bear and justify a treatment which would prove injurious in other instances, and I believe that the general treatment suitable for cases of sporadic pharyngeal diphtheria is also well adapted, with the addition of special means required by the mechanical obstruction of the larynx, to the treatment of sporadic membranous croup.

I shall add but a word on the argument of contagion. There is still need

of careful clinical work here, and the subject is now full of difficulty and obscurity. When epidemic diphtheria assumes the laryngeal form, the disease is clearly infectious or contagious, as is the pharyngeal form. When, on the other hand, pharyngeal diphtheria occurs in its mild sporadic form, any evidence of infectiousness or contagiousness is often wanting. I have known a mother, affected with an undoubted attack of this form of the disease, to nurse her child of thirteen months throughout the entire course of the disease without communicating it to the infant. I would refer, on the other hand, to the case of apparent sporadic membranous croup, above quoted, which was the cause, seemingly, of severe diphtheria in a younger sister. Is there anything in the anatomical conditions of the larynx and pharynx respectively—the much richer lymphatic supply of the latter, and the greater tendency to putrefactive changes in all exudations in that part—which may influence the liability to constitutional poisoning, and also to infectiousness, differently in the two cases?

I have no desire to assume a partisan position on this subject. I would be understood only as saying that the evident strong analogies between the two forms of disease, and the want of conclusiveness, as it seems to me, of the arguments in favor of their essential dissimilarity, make me feel it hazardous in the extreme to assert that they are radically distinct affections; and that I find myself more and more inclining to the view that they are only different forms or types of one pathological condition.

Dr. Henry Gibbons, of California, said:—When you, Mr. Chairman, and myself attended lectures in this University, no such word as diphtheria was known in the English language. Since then we have, by slow degrees, long study, and diligent practice, become convinced that there are two distinct forms of disease—one which we know as croup, and the other as diphtheria. Years ago we invariably bled for an attack of croup, and nearly always cured it.

Dr. J. J. Woodward, U. S. A., said:—I would like to ask Dr. Smith if, in preparing his paper, he consulted the first or second edition of Rokitansky's work? I thought from the reference to this eminent pathologist's views that his later edition, in which he speaks of diphtheria, had not been consulted.

Dr. C. J. Hare, of London, said:—This question of the identity or non-identity of croup and diphtheria is receiving a great deal of attention on the other side of the Atlantic as well as on this. At this time there is a sub-committee of the Royal Medico-Chirurgical Society of London investigating the subject. I admit that we should search after truth, but I think that medical men spend a great deal of time in re-determining questions that have already been determined. I think that after hearing the paper just read, there can be no doubt about there being two diverse and distinct diseases. The microscope has failed in other cases as well as in this. There appear to be distinctions which it is impossible to overlook. The symptoms of the two diseases have been so fully entered upon by the author of the paper that it would be out of place for me even to recapitulate those which are, as I conceive, distinctive between them; but there are two circumstances or conditions which, taken alone, prove to my mind the diversity of the two affections. I allude to the contagiousness of diphtheria, and to the paralytic affections which frequently result from it. Those who knew croup some thirty or forty years ago, and before the prevalence of diphtheria, will remember that the disease they then knew was never contagious, and was never followed by paralytic affections. Nor do the old authors, who described so graphically the symptoms of croup, ever mention these points. Will any one venture to say that if the contagiousness and the affections I have alluded to had been part and parcel of croup they could possibly have been overlooked, or could have failed to be described? No; they were not referred to, for the simple reason that they did not exist; and they did not exist then, because the disease at that time known was true croup and had no such symptoms; whereas, in recent years, we have also had to deal with another and different disease—diphtheria, of which contagiousness and the

sequelæ I have named are characteristic conditions. Our treatment has been modified, not because one disease has run into the other, but because we have two distinct diseases to deal with. The result as regards treatment, leaves no doubt whatever in my mind as to the non-identity of these two affections.

Dr. R. P. HOWARD, of Canada, said:—I cannot believe with the last speaker that this matter is so definitely settled in the minds of the scientific world. The fact that the Medico-Chirurgical Society of London has just appointed a committee to inquire into the matter proves this to be so, and the circumstance that the French school still regards membranous croup as laryngeal diphtheria, proves that the scientific mind is not agreed upon the question. I think that there is a good deal of truth expressed in the paper read on the subject, and that we will have to work honestly and fairly for a long time to come, before we can controvert some of its statements. If a large number of cases of so-called membranous croup were investigated after death, we might have the data by which to arrive at some truth on the subject.

Dr. W. OLDRIGHT, of Canada, said:—In 1865, while I was practising on the shores of Lake Huron, there was an epidemic of sore throat of a peculiar character. During that time I think I met with one case of true diphtheria. On a Thursday night, a young man became intoxicated, and lay out all night; he was attacked by the disease, and on Sunday morning gangrene set in, and by evening the line of demarcation appeared. Shortly afterwards he died of strangulation. The young man's brother was also attacked, and became paralyzed and remained so for about four months. Another remarkable case was that of a boy about eleven years of age, who on being attacked became perfectly black in the face and throat. His face and ears were swollen terribly, but his intellect remained perfectly clear. He died in two or three hours.

Dr. R. BARTHOLOW, of Cincinnati, said:—As a clinician I have held that the differential diagnosis of croup and diphtheria rested on three conditions—the local affection, the constitutional state, and the sequelæ. In croup, the exudation or false membrane lies in contact, merely, with the mucous membrane; in diphtheria, the exudation extends into and involves the epithelial layer of the mucous membrane, and the neighboring vessels, especially the lymphatics, are crowded with bacteria. Swelling of the sublingual and submaxillary glands accompanies various faucial inflammations, but in diphtheria the chain of lymphatics lying under the sterno-cleido-mastoid muscle is involved, while it is not in croup. As respects the constitutional state, the adynamia is much more strongly marked in diphtheria than in croup, and bears no proportion, necessarily, to the extent of the exudation in the fauces. No sequelæ follow croup. When the local process in the air passages ceases, the disease is at an end. On the other hand, in diphtheria, various sequelæ follow—albuminuria, paralysis, etc. Donders, in his Anomalies of Refraction and Accommodation of the Eye, makes the capital observation that the ocular and other paralyses which follow diphtheria are not determined by the amount of the faucial exudation, and often follow in cases which were supposed to be ordinary cases of sore throat, and in which no exudation had been observed. The contagiousness of diphtheria appears to be well established. If this be admitted it constitutes a fourth means of diagnosis.

Dr. T. L. MADDIN, of Tennessee, said:—In a recent number of the British and Foreign Medico-Chirurgical Review, the unity or duality of croup and diphtheria are fully considered: and from this it appears that recent authors of merit, treating upon the subject, leave the question in doubt. Thus it is evident that in the minds of many there are intimate links of connection between the two affections, if indeed, they are not grades of the same disease. With a large clinical experience, my convictions are clear that pathologically they have no kinship. Croup is a local disease, and its fever symptomatic; its etiology is various, even a common cold often causing it; its nature a local inflammation, with a false membrane strictly on the surface, and never undergoing necrosis. Diphtheria has a specific etiology, and is an essential fever.

Its false membrane, occurring mostly in the pharynx and tonsils, often invades the nasal, laryngeal, and bronchial mucous membrane. It penetrates the mucous and often the submucous structure, and undergoes septic decomposition. It may form on any portion of the body where there is a lesion. The fever is adynamic, and the convalescence slow. Albuminuria is present as in scarlet fever. The treatment of the two is totally different. I am, therefore, clearly of the opinion that croup and diphtheria are distinct diseases widely separated from each other.

Dr. H. P. Ayres, of Indiana, said:—I have seen croup prevail largely, and yet no diphtheritic symptoms accompany it: but I have never yet seen diphtheria prevail without croupy symptoms attending it. I do not think the disease is contagious, although it may be classed as such. I have seen cases in which one of a family was attacked and died, while the others escaped. Had the disease been contagious more than one would have been affected.

Dr. C. C. Hamilton, of Nova Scotia, said:—I have had experience with both diphtheria and croup, and think there cannot be any very great similarity between the two. I have had one or two cases which would tend to prove that croup is contagious, but as a general thing it is not. I have observed that since diphtheria has prevailed croup has been a much rarer affection than formerly.

DO THE CONDITIONS OF MODERN LIFE FAVOR SPECIALLY THE DEVELOPMENT OF NERVOUS DISEASES?

BY

ROBERTS BARTHOLOW, M.A., M.D.,

PROFESSOR OF THE THEORY AND PRACTICE OF MEDICINE IN THE MEDICAL COLLEGE OF OHIO.

"THE wear and tear of our modern civilization," is a current phrase which indicates the general belief, lay and professional, that the struggle for existence in our time imposes an excessive and consequently injurious labor on the brain and nervous system of man. That the injury thus done manifests itself in an increased production of nervous diseases, seems to be generally conceded. Without having bestowed much reflection on the subject, I had accepted this popular view; but when I came to investigate the facts which are available for the solution of the problem, in preparation for this paper, I felt obliged to change my opinions. To the question "Do the conditions of modern life favor specially the development of nervous diseases?" I reply in the negative.

At the outset, it must be admitted that the evidence is largely presumptive. No statistical data have descended from ancient times, and, indeed, as respects so recent a period as the last and the present century, an exact numerical expression of the relative prevalence of nervous diseases, is not possible. In the absence of statistical evidence, the inquiry must be directed into other channels. An approximation to the degree of current familiarity with mental and nervous maladies, may be made by a study of the references to such diseases in the ancient secular writers. The actual state of knowledge of mental and nervous maladies, as compared with other diseases (of women, for example) will be exhibited by the ancient medical writers.

Insanity is distinctly portrayed in some of the characters of the Greek drama. The tragic story of Orestes furnishes the material for two of the most powerful dramas of the Grecian stage. Both by Æschylus and Euripides, is the hero, Orestes, made to become insane by remorse after the death of Clytemnestra. The form of insanity which they depict is acute mania, and after a certain period reason is restored. Probably the best picture of mania which has descended to us from the ancient world, is the Ajax of Sophocles. This is delineated with a master hand, familiar with the malady described. Indeed the three dramatists exhibit a degree of familiarity with the salient features of an acute maniacal attack, which could only have been obtained by a personal study of the paroxysms. We obtain glimpses from the comedies of Aristophanes, that cases of senile dementia were not unfrequently subjects of judicial investigation. In his comedy of "The Clouds," which was directed against the sophists, and especially against Socrates, it is indicated that the young men of Athens employed such means to be rid of troublesome seniors. It is an historical fact that Sophocles in his old age was the subject of an inquiry into his mental condition, instigated by his sons who wished to obtain possession of his property. Even Socrates was the subject of a delusion—his inward voice, *dæmonium*—which guided all his actions,

however trifling, and to which he invariably deferred. The *dæmonium* of Socrates has been the subject of an immense deal of speculative subtilty. Without presuming to decide a question so surrounded with difficulties, I may at least express an opinion formed after an examination of all the sources of information within my reach: To me, this voice, inward mentor, conscience, or *dæmonium*, appears to be a hallucination. It should be remembered that Socrates was given to introspection, and had a character full of eccentricities.

In Grecian and Roman mythology, madness is frequently inflicted for disregard of the commands of divinities, in accordance with the popular notion that the anger of the gods is thus visited on man. Bacchus was one of the divinities who most used this means of punishment. He thus afflicted Lycurgus, of Thrace, and the three daughters of Prætus, because they declined to worship him. These insane women are represented to have wandered in the fields like cows, and, quite in accordance with what we now know of the contagiousness of imitation, many Argive women went mad and did the same thing. The "heaven-inspired Cassandra" was doubtless insane, as the Trojans believed. It is a very old trick to feign insanity; Ulysses was the first on record to attempt it.

In the ancient secular writers references to the "sacred disease" are very numerous. Herodotus chronicles the fact that Cambyses was afflicted with this malady, and, very remarkably, he attributes the cruelties practised by this ruler to the mental state induced by the epileptic paroxysms. Gallius and Macrobius quote from Hippocrates in regard to the "sacred disease." In the former occurs the curious statement (attributed to Hippocrates) that the sexual congress is a condition of the body not unlike the epileptic paroxysm. Horace, in his epistles, describes melancholy and paralytic tremor.

Erb infers that neuralgia must have been comparatively rare in ancient times, because "Aretæus is the first who gives a recognizable description of it."[1] Yet Socrates, in the Phædo of Plato, is made to utter some remarkable thoughts on the relationship of pleasure and pain. "What an unaccountable thing, my friends, that seems to be, which men call pleasure; and how wonderfully it is related towards that which appears to be its contrary, pain; in that they will not both be present to a man at the same time; yet if any one pursues and attains the one, he is almost always compelled to receive the other, as if they were both united together from one head." These observations do not, it is true, prove the existence of neuralgia in ancient times, but they show that the acute-minded philosopher had reflected profoundly on the nature of pain, anticipating, in his conclusions, modern knowledge of the functions and attributes of the sensory nerves. These examples from the secular writers must suffice. Doubtless most of the members of this learned body will recall other and, it may be, more pertinent instances; but I must pass to consider the state of knowledge of nervous diseases shown by the medical writers of antiquity.

The writings of Hippocrates furnish us with numerous references to the more important nervous maladies. In the Prognostics, is delineated with admirable fidelity and brevity that form of delirium in which the patient picks at the bedclothes and objects in the air. In the Regimen in Acute Diseases, there is a distinct allusion to trembling delirium due to vinous excess. In the book of Epidemics, cases of "phrenitis" are

[1] Ziemssen's Handbook, vol. xi.

given, the main features of which are much like those of modern cerebro-spinal meningitis. The earlier writers made no attempt to differentiate in the forms of intra-cranial inflammations, for reasons which are perfectly obvious; although under the term *sphacelus* of the brain Hippocrates probably meant *ramollissement.* In the Aphorisms, we find a great many very acute observations on the signs and symptoms of many nervous affections. The sleep which approaches coma, and the sleep which puts an end to delirium, are described, and the prognostic value of sopor and insomnolence clearly stated. The insensibility to pain manifested by the insane is recognized. Hippocrates declares that the prognosis of insanity is more serious after forty years of age, a fact which, we must admit, is generally true. "It is better that a fever succeed to a convulsion, than a convulsion to a fever," is an undoubted truth, which indicates that Hippocrates recognized the clinical difference between those convulsions which announced the onset of a fever, and those which came on at the termination of an acute intra-cranial inflammation. He indicates his acquaintance with aphasia in various aphorisms which refer loss of speech to injuries of the head, vinous excess, etc. He frequently alludes to vertigo, apoplexy, and tetanus, and is minute on the subject of epilepsy, the prognosis of which, he informs us, is more favorable when the disease occurs in the young than when in the old. In a description of the effects of venery, Hippocrates draws a picture of nervous symptoms not unlike those belonging to the first stage of spinal sclerosis. It is known to all here present how pronounced are the sexual symptoms in Duchenne's first stage of progressive locomotor ataxia.

Some of the medical writers subsequent to Hippocrates are more minute and systematic in their descriptions of nervous diseases. Aretæus, who was most probably a contemporary of Galen, describes *tic douloureux* (On Cephalæa), vertigo, and the vertiginous sensations which accompany various intra-cranial diseases, epilepsy, melancholy, mania, ecstasy, apoplexy, paraplegia, hemiplegia, and paresis, and mentions disturbances of the functions of the cranial nerves such as are produced by intra-cranial tumors. The most complete account of nervous diseases that has descended to us from the ancient world is found in Galen.[1] The different varieties of headache are very admirably depicted by this writer, and he indicates his acquaintance with the fact that the symptoms are associated with various intra-cranial lesions. He treats of abscess, meningitis, coma-vigil, catalepsy, hysteria, melancholia, mania, imbecility, senile dementia, vertigo, epilepsy, apoplexy, paralysis, local paralyses, spasms, tetanus, paralytic tremor, etc. Writers subsequent to Galen, for many centuries, as is well known, adopted his descriptions. It would occupy too much time to give a detailed account of the opinions of other and less authoritative ancient medical writers. It must suffice to state that Aëtius, Oribasius, Alexander, Cælius Aurelianus, Celsus, Avicenna, and Rhazes, besides other less important ancient physicians, treat of nervous maladies at very much the same relative length. It is quite evident, then, that various diseases of the nervous system were perfectly familiar to the writers of the ancient world.

If we compare the manner in which the ancient medical writers discussed the various diseases with which they were acquainted, we find that affections of the nervous system occupied as much space in their works as the diseases of other parts. Probably the knowledge of the

[1] De Compositione Medicamentorum secundum Locos.

ancients, as compared with modern acquirements, was more full and exact on the subject of the diseases of females than of any other group of maladies. Some instruments of precision which have contributed so largely to the development of gynæcology, were known to and used by the most ancient practitioners of whom we have any knowledge. The speculum, the uterine sound, and the pessary, were, as is well known, only rediscovered in modern times. An attentive examination of the ancient books on female diseases must convince any one that women have always suffered from the physical infirmities to which, in our day, they seem to be specially liable. The ancient physicians had every opportunity, we may suppose, to become practically familiar with female diseases, and the information conveyed to us in their writings is marked by the accuracy of detail only secured by faithful observation. When we compare the amount of space devoted to nervous and female diseases, respectively, it is evident that the former are treated with as full detail as the latter. If we take the works of Paulus Ægineta, who, according to his own statement, "compiled his collection from the works of the ancients," without omitting "any one distemper," we can see that affections of the nervous system occupy quite as much space as diseases of women, and are treated as intelligently.

When the ancient writers allude to the causes of diseases affecting the nervous system, they are said to be heat, cold, injuries, and excesses in eating, drinking, and venery—just such causes as in modern times are held to be influential. The most superficial survey of ancient society must convince any one that the nervous system of man was, in those days, exposed to extraordinary trials. The writings of Aristophanes, of Lucian, of Athenæus, amongst the Greeks, of Martial and of Juvenal amongst the Romans, give us hints of a licentiousness to which the most debased societies of modern times afford no sort of parallel. The political status of the ancient civilized communities was never permanent. Wars and revolutions, characterized by the greatest atrocities, occupied the restless citizens of the Grecian and Roman States. At home, games, public amusements, constantly recurring political excitements, the worship of Venus and Bacchus with their attendant orgies; abroad, wars, conquest, and plunder, were the occupations of Athenian and Roman citizens.

The minute subdivisions into which the medical art was parcelled amongst the ancient Egyptians, and later amongst the Romans, indicated that in those times diseases were very rife. In Cicero's age[1] the only divisions were three—physicians, surgeons, and oculists; but when Galen wrote,[2] the bad example of Thessalus had filled Rome with a great crowd of hungry specialists in every possible field of medical practice. There were specialists in remedies, as well as in diseases, and in the diseases of every known organ of the body. There were specialists for the globes of the eyes, and for the eyelids; for the uvula, and for the tonsils; for the external ears, and for the internal ears; for palsy, dropsy, stone, and skin diseases; for children, and for old people. There were apostles of the movement-cure, or those who treated rheumatic and paralytic troubles by gymnastics, *massage*, and frictions. Galen contemptuously styled these multitudinous charlatans, the asses of Thessalus; for this magnificent, impudent, and successful quack had declared that he could teach any doctor in six months all that he needed to learn. We obtain from Pliny a lively picture of the ignorance and rapacity of these specialists:[3]

[1] De Oratore. [2] Methodus Medendi. [3] Historia Naturalis.

"I will not speak of their avarice, their swindling bargains made with patients in an extremity, the imposition laid on suffering, the earnest money, so to speak, of death, the secret retainer fees," etc. Alluding to the same class, Galen affirms that the doctors in Rome differed from highwaymen only in the fact that the former lived in the city, and the latter camped out in the mountains.

These facts indicate, I think, that the diseases incident to Roman life were very numerous, and hence the demand for physicians; otherwise the supply had not been so abundant. In this strange medley of specialists, there seem to have been as many, comparatively, devoted to maladies of the nervous kind as to other diseases, and certainly during the times of Galen and Pliny there were in the social and political condition of the Roman people powerful causes in operation to produce these affections.

From the thirteenth to the sixteenth centuries, there occurred in Europe epidemics of purely nervous maladies such as the world had never before witnessed. In the graphic pages of Hecker, we learn that the dancing mania, in Germany and Holland, tarantism in Italy, and the malady of the *Convulsionnaires*, in France, involved great numbers in the wildest excesses. Such moral epidemics are possible only in such a state of society as existed in the mediæval times—an age of faith and reverence, but ignorant and superstitious. During the same period great epidemics of cerebro-spinal meningitis devastated various parts of Europe, notably near the close of the fifteenth and at the beginning of the sixteenth centuries. No additions during the middle ages appear to have been made to the knowledge of Galen. In a voluminous work on "The Generall Practice of Phisicke," "compiled and written by the most famous and learned Doctor Christopher Wirtzung," and published near the close of the sixteenth century, the descriptions of Galen are closely followed. In his commentary on "the braines and all that concerneth them," the learned Doctor includes loss of memory, vertigo, phrenitis, mania, melancholia, dementia, palsy, tremor, spasm, incubus, epilepsy, and sciatica. It is perfectly obvious that the state of medical knowledge then existing did not admit more accurate differentiation in nervous maladies.

The present condition of neurological medicine has been reached only since the physiology of the nervous system has been adequately studied within the last fifty years. Until Bichat had laid the foundation of general anatomy, physiology had scarcely existed. The brilliant results attained by the study of the nervous functions by the modern methods of research, and the great development of morbid anatomy, have stimulated investigation of the diseases of the nervous system, and to the operation of these causes must be attributed the remarkable advance in neurological science. Diseases of the nervous system have been accurately differentiated, and have been elaborately studied both from the clinical and pathological standpoint; but it is more than doubtful if any have been actually discovered in modern times. Various attempts have been made in France, England, and the United States, to determine, by the statistical method, whether an actual increase in the number of insane, relatively to the growth of the whole body of the population, has taken place in modern times. It is extremely difficult to make a thoroughly exact census of the insane. Each succeeding registration is probably more exact than those which preceded it; but even in England it is not claimed that the returns are more than an approximation to exactitude. It is undeni-

able that in each decade a small increase in the number of insane has been noted; but it is conceded in every report on the subject that the registration, becoming more and more exact, makes an increase which is merely apparent. Moreover, a more humane and abundant provision for the insane, and the increased facilities for communicating with asylums, induce the friends of these unfortunates to entrust their keeping to the great institutions now provided for the purpose.

If the kind of evidence which I have submitted has any value in deciding a question of this kind, it must be admitted that the various forms of nervous disease, including insanity, are not more numerous, relatively, now than in ancient times. If, as is probable, nervous diseases are not more numerous than they have always been, an inquiry into the conditions of modern life supposed to have increased them, may appear to be unnecessary. A candid examination of those conditions will demonstrate, I think, that their influence has been greatly exaggerated. The abuse of stimulants and narcotics, although not unknown to the ancients, is commonly held to be more extended in modern times. Certain poisons, dye-stuffs, cosmetics, and deleterious metals of various kinds, enter more largely into domestic use than was the case in former ages. Our modern means of intercommunication by railways, subject the nervous system to a degree and kind of concussion unknown to the people of ancient times. Modern habitations, with their appliances for heating and lighting, social customs, diet, and all the methods of an enlightened hygiene, are very different from those used in the most polished periods of Egyptian, Grecian, or Roman life.

It is probably an error to suppose that alcoholic excess is more common in our day. Wine was the beverage chiefly used in ancient times, as it is now in the wine-growing countries bordering the Mediterranean. Drunkenness is an uncommon vice in those countries to-day. The feasts of Bacchus, in ancient times, were scenes of extraordinary drunkenness and debauchery, which must have initiated thousands into habits of intoxication. The god visited madness on those who refused to engage in the bacchanalian rites. The symposia and orgies, in which the upper classes, Grecian and Roman, engaged, consisted in an abandonment to the vinous intoxication. That such indulgences brought upon the victim the usual punishment, is evident from the references in Hippocrates to delirium tremens and aphasia from vinous excess. It cannot be denied that the chief factor in the causation of insanity, and an influential one in the production of other nervous maladies, in our day, is alcoholic excess, but it must have been equally so in ancient times.

Although the properties of opium were certainly known in the first century, it was not used as a means of intoxication until the second, and then, certainly, to a very moderate extent. Its systematic use in civilized communities is a comparatively modern vice, and even now, although indulged in to an extent which must awaken solicitude, is as yet confined to an inconsiderable part of the population. Opium smoking has attained to extraordinary proportions in China, and it is estimated that twenty per cent. of the population of that country is now addicted to it. A recent observer concludes "that disorders of the nervous system in a general sense, are by no means infrequent amongst the Chinese, . . . the probabilities are that the prevalence of diseases of the general nervous system in China bears some proportion to the prevalence of the same disease in Europe, and other regions, . . . but that cases of alienation of mind, idiocy, lunacy, fatuity, and generally

speaking, insanity, are strikingly few, if we leave suicides out of the reckoning."[1]

Tobacco has now been used by civilized peoples for three centuries. The greatest evils were supposed to be produced by it when Sir Walter Raleigh and his companions first made it the fashion. The large experience and observation of its effects which have been acquired, demonstrate that its moderate use produces no ill results, and that the evils which come of immoderate indulgence are quickly recovered from when the narcotic is suspended. As the disturbances in the nervous system induced by tobacco are functional, we have in this fact an explanation of the apparent freedom from injury of those addicted to its habitual use.

Various modes of contamination by poisonous metals—lead, copper, mercury, etc.—are possible by reason of the employment in domestic life of articles of necessity and luxury, containing them, and by the various applications of these metals in the industrial arts. Individual examples of deleterious results—affections of the nervous system—are not uncommon, but no general or diffused injury has occurred, or probably can occur.

The daily railway travel of a considerable portion of the population of civilized countries, has been supposed to exert an injurious influence on the nervous system. The jar and concussion, the deafening noise which assails the ear, and the rapid movement of objects which fatigues the eyes, are supposed to impair the integrity of the nerve centres. One of the diseases alleged to be caused by railway travel is progressive locomotor ataxia. If ill results are thus produced, they ought to be seen in the locomotive engineers. On the contrary, the Brotherhood of Locomotive Engineers is a body of men who are remarkably free from nervous ailments, and who are indeed distinguished for their vigorous health.

As respects the social and domestic conditions of modern life, it can hardly be disputed that modern man is in every respect more favorably situated than was his ancient prototype. If statistics are worth anything, it must be admitted that the improved hygienic conditions of modern society have lessened the sickness and mortality rates, and have increased the longevity of man. The epidemics as described by Hippocrates; the plague as depicted by Thucydides; the black death of the middle ages; the ravages of smallpox in the last century, have been imitated, but not at all equalled by the Asiatic cholera in this century. Those great epidemical waves of cerebro-spinal meningitis which formerly overflowed Europe are no longer possible. A great moral epidemic, like the dancing mania, would be as much a solecism in this nineteenth century as a revival of the crusades.

The Geneva vital statistics, with the observation of four centuries, and the experience of the great life-assurance societies, based originally on the Carlisle tables, seem to have established the fact of the increasing longevity of man. If man is living under more favorable hygienic conditions, and is less vulnerable in his bodily constitution, it must be admitted that he is improving rather than degenerating. Is it not to the last degree improbable that one system of the body should manifest signs of premature decay, and the rest exhibit unwonted vigor? Such a supposition is all the more incredible when we come to reflect on the important position which the central nervous system holds in respect to the nutrition and healthy functional activity of other parts of the body. It

[1] Dr. George Hearn, Journal of Mental Science, April, 1875.

is as little likely that more men, comparatively, are bald in our day than were so in ancient times. These facts seem conclusive against the views of those pessimists who maintain that the nervous system of man is degenerating under the teasing influences of our modern civilization.

Instead of degenerating, it seems highly probable that the brain of man, like his bones and muscles, is capable of more work than formerly. Modern thinkers rival the metaphysical subtlety of Aristotle, and an ordinary man requires to carry an amount of material as the usual furniture of his brain which would have conferred immortality on an Athenian. The brain in its state of functional activity, indeed, illustrates most aptly what has been styled the principle of least action. A large part of our mental processes are carried on without our consciousness—a state of functional activity to which it is the fashion to apply the term "unconscious cerebration." So nicely adapted is the organ to the work it has to perform, that it accomplishes its tasks without any jar, without indeed disturbing its very sensitive tenant, the Ego. The wear and tear of our modern civilization no more affects the integrity of this organ than the discussions in the groves of the academy, nor than the political dissensions of the Grecian and Roman states.

The following conclusions seem to be warranted by what has gone before:—

I. Nervous diseases, in the most common forms, have been distinctly recognized by lay and medical writers from the earliest periods.

II. They appear to have been as prevalent, relatively, in ancient as in modern times.

III. The sickness and mortality rates having lessened and the longevity of man having increased in modern times, it is highly improbable that the nervous system of man has become more vulnerable.

IV. In modern times nervous diseases have been more accurately studied and differentiated.[1]

Discussion on Dr. Bartholow's Paper.

After the reading of the preceding paper, Dr. Traill Green, of Easton, Pennsylvania, said:—No doubt the ancients were well acquainted with nervous diseases. Apoplexy was well known in Scriptural times, and we find that many characters in Biblical history suffered from it. When a man is attacked by apoplexy now, people are apt to say that he has suffered from overstrain. But we find that the ancients suffered from the same affection, and they had not the business strain of the present day. Statistics compiled by men familiar with the subject, and endorsed by mathematicians, show that there is an apparent increase in deaths from nervous diseases among the policy holders of insurance companies; but this is attributed to the fact that more old people insure now than formerly. The percentage of insanity is just $\frac{53}{100}$ of one per cent., and the number of apoplectics is not large. I have closely observed nervous diseases in my own neighborhood, and out of about fifty persons whom I have known to die or suffer from apoplexy, or palsy, not one could be said to have owed his attack to the result of overstrain. The ages of these patients varied

[1] Thirty minutes was the limit fixed by the executive committee for the length of papers read in the sections. The writer regrets that he was not aware that deviation from this limit would be permitted, for he would otherwise have presented his argument more in detail, and would have entered more fully into the statistical data which exist as to the comparative prevalence of nervous diseases in the first and latter halves of the nineteenth century.

from 58 to 92 years, at the time of attack, and they were from all walks of life.

Dr. Henry Gibbons, of San Francisco, said :—There is nothing in the records of antiquity nor in modern statistics to settle this question. The statistics of insurance companies, derived from selected subjects, are of no avail for the purpose. Mortuary statistics refer only to deaths, and not to the prevalence of diseases. Even if it were proved that nervous disorders caused as great a proportionate mortality in former times as now, it would not reach the question; for with the great advance in pathology and treatment, the mortality ought to diminish. If Dr. Bartholow were to reside a year or two in California, he would change his mind as to the increase of nervous disorders in that quarter. The increase is conspicuous, and there are causes operating there which must have that effect. With a large portion of the population, the home and family influences are wanting, and men in trouble and difficulty are adrift in the world—no wife, no parents, no children to anchor their troubled spirits. Passions of all kinds get control. Very recently the wild speculations in mining stocks, by which fortunes are made or lost in a day, have developed a notable number of cerebral cases, ending in suicide or insanity. Whether modern society in old and settled communities exhibits any increase of nervous disorders, I am not prepared to say; but as like causes produce like effects, and as there is every reason to believe that moral and physical causes of a disturbing character are more abundant in modern times than formerly, we might reasonably infer that disorders of the nervous system would be more frequent, though their aggregate mortality may not be greater. It must be conceded, however, without qualification, that in newly-settled countries, and all around the outskirts of the old civilization, in all parts of the world, the circumstances of society are more or less similar to those I have pointed out in California, and that they must lead to similar results.

Dr. Wm. B. Neftel, of New York, said :—I have no doubt that the causes of nervous diseases have increased in modern days. The subjects of these affections transmit them to their descendants in an aggravated or modified form. We must also consider the law of development. The brain's intellectual sphere has been enlarged, and, with increased mental activity, we have greater liability to nervous diseases. The common use of alcoholic stimulants at the present day, is, both directly and indirectly, a cause of nervous affections. Syphilis, another cause of nervous diseases, is not found to have existed in former times, while now it is very common. The records of the Pathological Institute of Berlin prove conclusively that many fatal diseases of the brain are due to syphilis.

Dr. Thomas L. Maddin, of Nashville, Tenn., said :—I agree with the author of the paper that there are no new diseases to which man is subject, for all disease is but an error of the tissue or function of an organ. But because of education and the surroundings of modern life we may have new modifications of disease, and we often have a physical basis on which to rest those modifications. The exercise of any organ of the body will increase its size and structure, and in that way may modify the diseases of an organ. For instance, a man living luxuriously, and constantly using stimulating condiments and alcoholic drinks, will in the course of time have his liver in an abnormal condition, and then there is a physical basis for organic and functional hepatic disorder. He is predisposed to diseases which another man, living on frugal, plain diet, while subject to the same affections, is not so likely to have developed. People are different now from what they were two thousand years ago, or in their primitive state. People in civilized life differ from savages in reference to the development of the nervous system. Take a man on a plantation, with no education, and no elevation of thought, and take another who has been precociously educated from childhood; the brain of the latter is in a state of hyperæmia; his nervous condition has been stimulated from the beginning; and there is an abnormal condition of his entire nervous system. It is educated

out of relationship to the other organs of his body. It has obtained an ascendency over his system which influences the functions of the other organs. Thus the highly educated and civilized man is more subject to nervous disorders than the quiet countryman.

Dr. A. B. Arnold, of Baltimore, said:—The etiology of all diseases is obscure, but particularly so that of diseases of the nervous system. I believe that the idea that nervous diseases are more prevalent now than formerly has originated with specialists. I have practised for thirty years, and am not aware that I have seen more cases of nervous disease during the latter than during the former half of that time. If the increase spoken of exists, it must be attributed to the progress of civilization, to the wear and tear of body and mind, and to the race for wealth. Intellectual men are generally long-lived. I believe that shocks are more detrimental than hard study, and, as pointed out by the reader of the paper, war and turmoil with all their attendant evils were the almost natural conditions of former times, while now they are comparatively rare. In modern civilization, the mind is better trained and disciplined. It is not so demonstrative in joy, nor so depressed in trouble. Discipline prevents the mind from being affected with shocks. I believe, although it is rather Darwinian to think so, that the nervous system accommodates itself to the strain put upon it—an accommodation of the inward condition to external influences, which is in favor of the present time. I am not aware that even special writers on the subject particularly ascribe insanity to a syphilitic condition; in fact, the subject is so extremely obscure that it is hazardous to express an opinion upon it. Again, medical men allow themselves to be too much influenced by the hue and cry of professional temperance orators. It cannot be scientifically proved that alcohol in the form in which it is at present used has a very marked influence in the production of nervous disease. I believe that, instead of drunkenness being a cause of mental disease, it is in nine cases out of ten only the first warning of its approach.

Dr. N. S. Davis, of Chicago, said:—This question is one of very wide scope, and one which it will be extremely difficult to determine with any degree of certainty, with our present knowledge. Even in this discussion, the fact has been brought out that in certain conditions of society there is to be found a marked increase of particular nervous diseases. The gentleman from the Pacific coast has indicated a condition of modern society which has a tendency to develop that form of nervous derangement that leads to insanity. Go back to the days of the Crusades, when all Europe was aroused by a religious mania, and was led forth to the battle field by hundreds of thousands, and you will find conditions which were likely to, and which doubtless did, produce special tendencies towards the development of mental disease. People talk about mental strain being a cause of mental disorder; about the intensity of our work: I have been led to think that very few brains ever wear out by work. The physiological law is growth; strength; compactness. If there is not some corroding influence to interfere with the law, you will seldom wear out your brains with work. Rush tells us of the ten years before the Revolution, when a large part of the male population of Philadelphia was aggregated in social clubs, eating four meals a day, and drinking intoxicating liquors at each; and he lived to see almost every member of those clubs go to his grave from the effects of apoplexy, paralysis, or dropsy: there was a development of nervous disease. The Revolution followed, there was excitement and war; the people were stripped of their property, and were compelled to labor and toil mentally and physically; and that particular class of nervous diseases almost disappeared.

No doubt some special nervous diseases have diminished, while others have increased. The reason for this increase of particular classes of disease is not our high state of civilization, nor our extent of learning; I doubt whether we have a student in America, to-day, who studies harder than some of the students of Greece and Rome, or even of the ancient Jews. I doubt whether

some of them did not think as deeply and persistently. And no doubt some of them suffered from mental disease, but not from thinking or study. I think Saul got his paroxysms of mental derangement, as a great many do to-day, from *wickedness;* not from study. It is not the hours we spend at books, or at business, that wear us out; much is attributable to our anxiety for wealth and show. When we put our whole heart on accumulating wealth, and the bubble bursts, it produces a severe mental anxiety. Large numbers of our students become lean and dyspeptic, and disordered in health, before they get half through college; why? Because they learn at an early period of life to go to the breakfast-table, and sip two cups of coffee and nibble a crust of bread as an apology for breakfast; thus endeavoring to substitute pure nervous excitation for materials to replenish blood and make tissne. It is the same with many lawyers and doctors, whose friends say they are killing themselves, and yet who do not devote to their professional duties as much time, by one-third, as others do, who are perfectly free from nervous disease. What is the reason? Because as soon as they take their meals they are puffing their tobacco, or chewing their *quids*, until they have their entire nervous systems saturated with a narcotic that cannot fail to produce retardation of molecular changes, thus acting upon the false notion that the *retention* of an *old atom* is equivalent to the *evolution* of a *new* one; and in a few years they complain of being worn out. They have retained the old atoms in the form of inert fat, which begins to find lodgment in the brain, or liver, or heart. If an artery gives way, and they fall from apoplexy or palsy, you give your certificate that they have died from one of these diseases, when the truth is that they have died from long use of alcohol and tobacco. Take these two influences out of the community, and you will have less nervons disease than the ancients, because the other influences are of such a nature that we can guard against them. We would live longer, the race would be healthier, and we would have fewer diseases of any kind. These things have stepped in and filled up the places of some things peculiar to the ancients. No doubt causes have been operating all through the world's history, sometimes making one form of mental disease more prevalent than another. Balance them up, and we may find that we are very nearly where we were in former years. Our advances in sanitary science, and in pathology, and in the treatment of disease, have lessened mortality and increased the duration of human life. If the prevalence is the same as in former times, then we must have more influences at work.

Dr. R. P. Howard, of Montreal, said:—I think that previous speakers have established the fact that nervous diseases are more common than formerly, owing to the use of stimulants; alcohol was used by the ancients, but tea and tobacco are modern, and are potential causes of derangement of the nervous system. Syphilis is another modern cause of nervous disease. One of the speakers has tried to ignore the importance of this, but its influence is well established. The undue attention of modern civilization to culture of the brain, over-developing it in relation to the other organs, may be another cause. Hereditary influences will wear themselves out, else every person would inherit some taint. A man may have too much work as well as too little. The men of to-day work faster than men in former times; everything is done in a hurry. The weight of evidence is in favor of the view that there is a tendency to an increase of nervous affections.

Dr. H. I. Bowditch, of Boston, said:—There are one or two points which have not been noticed. I am satisfied that the climate of this country is more stimulating than that of others. I infer this from the general effect it has upon the English race. The Anglo-Saxon race has grown thin and apparently more excitable than it was in the mother country. English people have found that they cannot safely drink to such an extent as they can in England. I have known cases in which Englishmen in America have been attacked by delirium tremens, from using quantities of alcohol which they had used with perfect impunity in England. Yet they were comparatively temperate men. Again,

there is the perpetual political excitement, affecting both our men and women, which has no existence in Europe. When an American goes to Europe, he gets into a state of quiescence which is perfectly delightful, but when he returns, even after spending six months there, the first sight of the pilot boat puts him into an excitement about the latest scraps of political news.

Dr. GREEN said:—No inference can be drawn from the frequency of suicide, as suicides are committed from other causes than the existence of nervous disease. The Welsh are more predisposed to mental and nervous diseases than other people of Great Britain, so that the question of race should be considered in connection with the subject.

Dr. W. SCOTT, of Cleveland, Ohio, said:—Our modes of travel induce diseases unknown to our forefathers. The custom of sending children to school at too early an age also exercises a pernicious influence. Children are taken from school at the time when they ought to be commencing their studies in earnest. The medical profession ought to take the subject of education in the public schools into serious consideration. Vicious systems of education are the cause of many functional disorders, and often lay the foundation for the development of nervous disease. Another feature of our modern civilization is the want of vigorous development, and this is more fruitful of nervous affections than chewing tobacco or drinking coffee. Plants require the light of the sun in order to grow, and our children should not be denied its blessings. Many houses, of even luxurious construction, are kept in a state of dungeon-like darkness, and children reared in such houses are not nearly so vigorous as the children of a country clown, who have at least the benefits of air and sunshine.

Dr. BARTHOLOW, in reply, said:—I think that the statements of specialists should be taken with a great deal of allowance. They seem to base the opinion that nervous diseases are increasing, upon the fact that they see more cases than formerly; but that is only the result of their individual business increasing, as they become settled in practice. Doctors never see as many cases in their first years of practice as subsequently. It has been asserted that syphilis is a modern disease; that is doubtful. Many causes of syphilis existed formerly, and there is no proof that the disease did not exist too. My great answer to all the arguments which have been adduced is that men are larger, stronger, and better in every way than in former times. A modern Englishman cannot put on the old armor. The body is stronger and stouter than it was, and men are able to do more intellectual work. If the Geneva statistics are worth anything, they prove that the longevity of man has doubled within three centuries. As to the effect of the climate of America, it is found that longevity is greater here than in England.

CONTRIBUTION TO THE ETIOLOGY OF EPILEPSY.

BY

WILLIAM B. NEFTEL, M.D.,

OF NEW YORK.

The remarkable progress made in our knowledge of epilepsy commences with the classical researches of Brown-Séquard in 1850.[1] As the results obtained by him are well known to the profession, I shall merely mention here a few of the more important points. After the division of one half of the spinal cord, or of one sciatic nerve, in the guinea-pig, the animal becomes epileptic in the course of several weeks, exhibiting on the injured side the so-called epileptogenic zone. This zone is characterized by a lowered sensibility, and is situated below the eye, especially at the angle of the lower jaw, and extending toward the neck and scapula. If the section be made through the entire cord, or through both sciatic nerves, the epileptogenic zone appears on both sides, and if the pedunculus cerebri be injured, the epileptogenic zone appears on the opposite side. The epileptic attacks sometimes occur spontaneously, but they can be called forth at any moment by irritating, or even touching, the epileptogenic zone. The artificially produced epilepsy is transmitted by inheritance to the descendants of the animal on which the experiment has been performed.

These facts are of immense importance for the study of epilepsy in general, though as yet they do not admit of a direct application to human pathology, with the exception of the hereditary disposition, which, however, had been already previously established. It is easy to presume that epilepsy can be brought on by injury of a sensitive or of a mixed nerve, and therefore also by injury of the sciatic nerve, or of the spinal cord, but it is not in accordance with the daily experience of physicians that affections of the spine or of the sciatic should cause epilepsy, with an epileptogenic zone. Thus amputation of the thigh (section of the sciatic) is not followed by epilepsy, with an epileptogenic zone. Again, W. Müller[2] has published a case in which the injury of the cord in the human subject much resembled the experiments of Brown-Séquard on guinea-pigs. A man received a wound in the back from a knife that penetrated through the cord; the patient lived forty-three days, exhibiting all the symptoms of injury of the cord on one side, but having no convulsions whatever, though at the autopsy it was found that the entire left side of the cord had been perfectly divided.[3]

[1] Brown-Séquard, Researches on Epilepsy, etc., Boston, 1857; also Journal de la Physiologie des Hommes et des Animaux, 1858–1860; Archives de Physiologie normale et pathologique, 1868–1872.

[2] Wilhelm Müller, Beiträge zur pathologischen Anatomie und Physiologie des menschlichen Rückenmarkes. Leipzig, 1871.

[3] I omit giving here examples of epilepsy caused by injuries of sensitive nerves, and will only mention that it remains as yet undecided whether the epilepsy in these cases is caused by neuritis ascendens, or by purely functional centripetal excitations. Thus in the case described by Virchow, the epilepsy was caused by an injury of the median nerve (neuritis interstitialis prolifera), and in Echeverria's case by a lesion of the ulnar nerve (neuritis).

In 1871, Westphal,[1] in repeating the experiments of Brown-Séquard, whose conclusions he confirmed in all particulars, found that guinea-pigs could be made epileptic by producing a commotion of the brain. By knocking the animal's skull against a solid object, or by inflicting with a small hammer (such as that used in percussion) one or several blows upon its head, the animal is seized with general tonic and clonic convulsions, quite identical in character with the epileptic attacks exhibited by the animals treated by Brown-Séquard's method. If the commotion is very intense, the blow being too violent, the convulsions are generally followed by the death of the animal from paralysis of respiration, the action of the heart still continuing for several minutes. If, however, the blows are moderate, the animals entirely recover from the first attack, but after the lapse of several weeks exhibit the epileptic state and the epileptogenic zone on both sides, exactly like the animals artificially made epileptic by a bilateral section of the cord or of both sciatic nerves. In young animals an attack is called forth by a few slight percussions with the hammer, while in grown, vigorous animals a considerable amount of force is required to produce the same effect.

When the blows are very slight, no real epileptic attacks follow, but, instead of them, what may be called abortive attacks, consisting of peculiar reflex movements. If one of the epileptogenic zones be pinched in such an animal, it scratches the place with the corresponding extremity, and, closing the eyes, turns the head toward the same side. Animals exhibiting abortive attacks can easily be made epileptic by repeating the same operation. The epileptic state and the epileptogenic zones appear generally four or five weeks after the commotion, and may last six months or longer, after which they gradually disappear, though a slight blow on the head can easily bring them on again. Sometimes the attacks manifest themselves spontaneously, but they can always be called forth by mechanical irritation of the epileptogenic zone on each side. The epilepsy artificially produced by cerebral commotion is also transmitted by inheritance.

In order to ascertain the anatomical lesion which caused the epilepsy after these experiments, Westphal removed the skin and periosteum, and, inflicting the blows directly on the bones of the skull, obtained the same result, viz., an immediate attack, followed later by the epileptic state and the epileptogenic zones. This shows conclusively that the sensitive nerves of the skin or of the periosteum have nothing to do with these phenomena. Moreover, the autopsy made by Westphal immediately after the first attack following the blow, did not reveal any lesion either of the skull, or of the cerebral hemispheres, or of the cerebellum. He found only capillary hemorrhages in the gray and white substances of the medulla oblongata and of the upper cervical portion of the cord. Though the experiments of Westphal apparently have some similitude with traumatic injuries of the head, in man, yet he rejects any application of the results of his experimental researches to human pathology.

On the other hand, in Billroth's case there was no neuritis, though the epilepsy was induced by a traumatic cause affecting the sciatic nerve. In the same way wounds and cicatrices may induce epilepsy by the irritation of sensitive nerves. Thus in a case described by Schnee, the epilepsy was brought on by a wound of the head, which left a very sensitive cicatrix the slightest touching of which would call forth an epileptic attack. The epilepsy disappeared after the excision of the cicatrix, in which microscopical examination revealed the presence of neuritis.

[1] Westphal, Ueber künstliche Erzeugung von Epilepsie bei Meerschweinchen; Berl. klin. Wochensch., 1871, No. 38, 39.

He says: "I am not acquainted with a single observation of cerebral commotion (in the human subject), in which convulsions are mentioned among its symptoms." [1]

Hitzig[2] has also produced epileptiform convulsions, in dogs, by injuring the cerebral cortex. There is no doubt that epileptiform convulsions can be called forth in various ways, especially by injuring sensitive parts, among others therefore some central nervous structures. But the epileptiform convulsions thus produced are by no means identical with epilepsy, which, besides convulsions, requires the presence of the so-called epileptic state. In speaking therefore of real epilepsy, we must exclude such convulsions as are caused by the sequelæ of injuries of the cortex (hemorrhages, inflammation, softening, etc.), as in the experiments of Hitzig, or in the cases of Hughlings-Jackson.[3] These latter seem also to have depended on lesions of the cerebral cortex, whereas the genuine epilepsy may exist without any palpable textural changes of the brain.

The following case, lately observed by me, presents unusual interest, inasmuch as it resembles in many respects the experiments on animals, and has besides the great advantage of giving in a precise manner the subjective feelings of the patient. It is not only interesting as regards symptomatology and treatment, but especially so as throwing some light on the etiology of epilepsy.

Mr. H. W. K., lawyer, 24 years old, of a healthy family, without any hereditary neuropathic disposition, was formerly quite well, intelligent, industrious, and very regular in his habits. During a riot in Washington, in July, 1869, a negro struck him with a loaded cane on the head. The first terrible blow brought him senseless to the ground, where he received several additional blows on the head. He was carried to his house in an unconscious state, and, according to the opinion of the attending physicians, remained during three days and three nights in a comatose and hopeless condition. The first blow, which rendered him senseless, was struck on the right side of the forehead, in the direction from the tuber frontale toward the right crista frontalis externa and linea semicircularis. Fortunately the patient had long hair at that time, and wore a straw hat, which undoubtedly weakened somewhat the force of the blows. To the same circumstance must be ascribed the absence of any injury to the skull, on which no marks of contusion were noticeable. The greatest danger that threatened the patient's life was the exceedingly feeble, scarcely perceptible respiration, which at times seemed entirely extinguished. The action of the heart was also very weak (pulse 20 in a minute), and immediate death was undoubtedly prevented only by the strenuous efforts of Surgeon-General Barnes, who remained day and night at the patient's bedside, energetically using all possible means of excitation and derivation.

On the fourth day the consciousness gradually returned, though the patient still remained motionless, and therefore was still considered unconscious. He could, however, hear and understand everything, and felt the greatest fear of being buried alive, hearing the physicians express their opinion of his hopeless condition, and of the fatal termination which must necessarily soon take place. At the end of the fourth day, he felt in the extremities a pricking sensation (formication), which gradually extended all over the body, and slowly disappeared on the fifth day. At the same time he began to make feeble movements with the extremities, and soon was able to contract all other voluntary muscles; but he could not swallow or speak until the end of the first week. During the second week after the commotion, the patient experienced the

[1] Loc. cit. p. 462.

[2] Hitzig, Untersuchungen uber das Gehirn. Berlin, 1874, S. 270.

[3] Hughlings-Jackson, West Riding Lunatic Asylum Medical Reports, vol. iii., 1873.

greatest inclination to sleep, and could not awaken spontaneously. According to the advice of his physicians, he was awakened at times, and prevented from sleeping continuously. He was extremely sensitive to noises, easily felt exhausted, and after the slightest exertion would become unconscious, and remain so during ten minutes, exhibiting at the same time convulsive movements. He remained in bed during three months, having the epileptic attacks at first very often, and then once in two or three days. At last his health commenced to improve, he had a better appetite, and could exercise in the open air. But even in the street he was seized several times by an attack, with pallor, loss of consciousness, and epileptic convulsions.

The most distressing symptom the patient suffered from was an intense headache, which commenced with the return of consciousness after the commotion, and has scarcely ever left him during six years. The seat of the pain is the right side of the forehead and the right eye, the spot of the intensest pain corresponding to the right crista frontalis externa, where it passes into the linea semicircularis. The pain at times increases spontaneously, and becomes unbearable, continuing so for days and even weeks, with but short remissions, and finally disappearing almost entirely. At the height of the paroxysm, the right eye becomes absolutely blind (the patient not being able to count fingers), the slightest touch of the painful zone is unbearable, and pressure upon it calls forth loss of consciousness, and convulsions, considered as epileptic by physicians who have witnessed them. Occasionally such fits occur spontaneously, without any pressure upon the painful zone, and the patient sometimes feels the approach of the attack, and has time to lie down carefully, though more frequently it comes on suddenly, and the patient falls without having taken any precaution. All the time the patient suffers from the violent headache, there is a complete analgesia of the painful zone, and the whole forehead appears pale and cold.

When the pain is severest, the patient lies motionless, suffering from nausea and vomiting, and scarcely able to eat anything, as these symptoms are invariably increased by food. The patient passes sleepless nights through the whole duration of the paroxysm, only getting occasional short naps, from which he awakens with increased pain. At last, under the constant use of hot applications to the head, the pain gradually disappears and the patient slowly recovers. He then remains in a comparatively healthy condition for days, weeks, or even months, with good appetite and the power of sleeping, and with the vision of both eyes normal. Nevertheless the painful zone remains sensitive, even during the intervals between the paroxysms, and the slightest touch, and especially pressure, can bring back the paroxysm of pain with all its distressing symptoms, the fainting, and the epileptic convulsions. The patient has always to avoid touching the painful zone, even while washing his face or wearing his hat. He can hardly read, his head and eyes often feeling heavy; he has also to avoid the rays of the sun, and every physical and mental exertion, and as a consequence, has been obliged to give up every occupation. Of late the paroxysms of pain have become more frequent; his memory, that used to be excellent, has begun to fail; he cannot always control his ideas with the former precision, and at times they appear so confused that he fears the development of insanity. In the course of the last three years, though he has been treated by many able physicians, and has used among other remedies a great deal of bromide of potassium and narcotics, nevertheless there has been a progressive aggravation of the disease, especially as regards the intellectual sphere and the frequency of the paroxysms of spontaneous pain.

Present condition: May 29, 1876. The patient is of middle size, with a well-developed skull and chest, and moderately developed muscles and panniculus adiposus; the color of the skin and of the visible mucous membranes is rather pale; the thoracic and abdominal organs are normal; pulse 70; respiration 18; temperature 37° C. He is now suffering from a comparatively mild attack of spontaneous pain, and has scarcely slept or taken any food during several days.

The painful zone extends over the right half of the frontal bone, the anterior lower portion of the right parietal bone, the upper portions of the greater wing of the sphenoid bone, and of the squamous part of the temporal bone, the right eyelids and eye. The slightest touch of this region cannot be borne, and the patient involuntarily shrinks from the approach of the exploring finger. The centre of the intensest pain (spontaneous, as well as produced by pressure) is the upper portion of the crista frontalis externa, and the adjoining lower portion of the linea semicircularis, extending about four centimetres in length, and half a centimetre in width. The right tuber frontale is also more tender than the rest of the painful zone, but there is no particular tenderness over the foramen supraorbitale. The painful zone does not extend below the eye. The patient is unwilling, for the sake of an experiment, to have the slighest pressure made upon the painful zone, but assures me that it has been done many times by mistake or carelessness, and has always been immediately followed by the intensest pain, with pallor of the face, loss of consciousness, and epileptic convulsions. The skin of the forehead is cooler than the rest of the face, it is quite pale, and analgesic; a prick with a needle is not felt. The right eye looks smaller than the left, and is almost blind. (Only quantitative light can be ascertained.) The right pupil is somewhat larger than the left, and reacts sluggishly; the right retinal vessels are narrower than those of the left side. The patient speaks very little, and almost without contracting the facial muscles, or moving the eyes; it seems as if he preferred to turn the whole head, instead of contracting the mimical and eye muscles. His physiognomy therefore lacks expression, or rather expresses stupor, though it is evident that he keeps the facial muscles immovable in order not to increase the pain. The patient has passed a perfectly sleepless night, and complains of nausea, general prostration, and heaviness of the head and eyes.

As every kind of medication that had been resorted to had utterly failed to benefit the patient, I decided to make a careful trial with the galvanic current. I applied the cathode of a weak current (two elements of Siemens) to the nape of the neck, and wanted to apply the anode to the painful zone, but the patient immediately turned away his head, before the electrode had touched the skin. Leaving the cathode at the same place, I then applied the button-shaped anode to the right auriculo-maxillary fossa, and, without interrupting the current, gradually increased its intensity. When six Siemens's elements had been introduced into the circuit, the patient remarked that the pain in the forehead began to increase, whereupon I slowly diminished the intensity of the current, the whole sitting lasting a little over a minute. He felt somewhat better after the treatment, and slept that night until 3 A. M., when he awoke with headache and nausea, the right eye being perfectly blind.

May 30. I tried again the galvanic current, but this time avoiding, as much as possible, fluctuations of the current-intensity by means of a rheostat, intercalated as an accessory current. The current was derived from ten Siemens's elements, the flat cathode being applied to the nape of the neck, and the button-shaped anode to the right auriculo-maxillary fossa; the resistances were gradually augmented in the rheostat, until the full current-intensity had passed through the body during fifteen seconds, after which the current was again slowly diminished by means of the rheostat, and imperceptibly broken. The effect of this treatment was quite surprising. As soon as the current began to flow with full intensity, the patient exclaimed that the pain had entirely left him, the head felt quite free, and the eyes became clear. The sitting had lasted about two minutes. The patient was quite overcome by the sudden disappearance of all the morbid symptoms; his features became movable, and the blindness vanished. He felt quite well the whole day, had a good appetite, could walk a great deal, and slept six hours. Though he awakened without pain, still, the next day, the head and eyes were heavy, and he felt the premonitory symptoms of an approaching paroxysm.

May 31. I repeated the same treatment, and with the same result; the

patient feeling invigorated, as if, according to his own expression, awakening from a long and refreshing sleep. I found on examination (which I had omitted the previous day), after the treatment, the following facts: Slight touching of the painful zone, with the exception of the most sensitive part (crista frontalis, etc.), could be easily borne; there was no trace of anæsthesia or analgesia in this region, but, on the contrary, a prick with a needle was most painfully felt (hyperæsthesia). It was quite surprising to find complete anæsthesia and analgesia of the left (healthy) side of the forehead, extending exactly to the median line. Moreover, on this side differences of temperature could not be distinguished by the patient, and on applying a piece of lint dipped in hot water, and another in iced water, he felt no difference on the left, healthy side, and could easily bear them both; whereas, on the painful zone, he could instantly and with great precision discover the least difference of temperature, the extremes of which were felt most unpleasantly. I ascertained, besides, that the left frontal muscle was paralyzed, the skin of the left (healthy) side remaining smooth when he wrinkled the forehead; also, that the left upper lid could not be perfectly closed.

June 1. I re-examined the patient, and convinced myself again of the correctness of the above-mentioned facts. I repeated daily the above-described treatment, applying in addition the button-shaped anode also to the left fossa auriculo-maxillaris.

June 20. The patient slept ten and a half hours, last night, and the foregoing nights, six or seven hours, which for years he has been unable to do. He feels quite well and strong, and has no pain; the head is clear, the vision of both eyes normal, and he can read very well, has a good appetite, and is able to walk considerable distances. On examination I find both eyes equal in every respect, and the vision normal. The painful zone admits of a moderate pressure, and even the most sensitive spot can be touched, though only very gently. The sensibility and sense of temperature in the painful zone still remain exalted (hyperæsthesia), and there is no trace of analgesia. However, a stronger pressure cannot be borne, especially by the most tender portion of the zone, and the patient still wears his straw hat obliquely toward the left side of the forehead, thus leaving the right side uncovered. The left side of the forehead cannot be corrugated, and is still analgesic, though a slight touch with the finger can be felt; differences of temperature cannot yet be distinguished.

The galvanic treatment was continued daily as before. viz.: flat cathode at the nape of the neck, and button-shaped anode at first to the right, and then to the left, fossa auriculo-maxillaris. Current-intensity seven to ten Siemens's elements, increased and decreased cautiously, though fluctuations of one element could now be easily borne. Current-duration about one minute, or one minute and a half, for each side.

July 3. The painful zone can now bear a considerable pressure, and even the most sensitive portion can be touched. The left side of the forehead can be wrinkled, though less than the right side, and the left eyelid can be perfectly closed. The senses of touch and temperature on this side have considerably improved, but are not yet restored. The analgesic area has been progressively contracting; the patient at first could feel the prick of a needle only at the lower part of the median line, then at the arcus superciliaris, and now the region of the left temple alone remains analgesic. The patient complains of no pain; all his functions are normally discharged; and his general health is quite satisfactory.[1]

I shall not enter into an analysis of the above described symptoms, as I had not the opportunity of observing the patient at the time of the accident, nor immediately after. Although the intelligent patient described with great minuteness all his subjective feelings, and as much as

[1] After thirty-one sittings of galvanic treatment the patient suddenly and unexpectedly discontinued his attendance.

possible gave the opinions of the physicians who then attended him; still we entirely miss the result of an objective examination as regards sensibility and motility; the ophthalmoscopic appearances; the condition of the pupils; the presence of sugar, albumen, or blood in the urine, etc. The patient did not even know during six years that the left (healthy) side of the forehead was anæsthetic and analgesic, with loss of the sense of temperature and with impossibility of wrinkling it (paralysis of the frontal muscle). On the contrary, he considered the painful zone as being analgesic, which may have been the case during the paroxysms of spontaneous pain, though during the intervals I always found this zone hyperæsthetic.

There can be no doubt, however, that the injury produced a cerebral commotion of the gravest kind, which threatened to terminate with paralysis of respiration, exactly as in the experiments of Westphal, when the blow on the head was too violent. This termination was prevented in our case merely by the energetic and successful interference of the attending physician. Whether with the cerebral commotion some transitory affection of the brain had taken place, cannot be decided with certainty. Thus the vaso-motor phenomena might have been ascribed to a lesion on the surface of the cerebral cortex, in which Hitzig[1] and Eulenburg and Landois[2] have quite recently discovered the existence of vaso-motor apparatus. Again, the existence of pachymeningitis might have been assumed with still greater probability in consideration of the somnolence of the patient during the second week after the accident, and the diagnostic value which Griesinger[3] attaches to this symptom, especially when it is found in conjunction with stupor, contracted pupils, and headache. On the other hand, the sudden and almost complete disappearance of all the morbid symptoms after galvanization, and their periodical absence, make very plausible the assumption that no permanent or grave lesion of the brain had been caused by the accident. This supposition is supported by the researches of Fischer,[4] who has shown that a mere traumatic reflex paralysis of the cerebral bloodvessels is sufficient to produce the phenomena of commotion of the brain. From the history of the disease, we have every reason to presume in our case the existence of such a reflex paralysis of the cerebral bloodvessels and not a permanent structural lesion of the brain.

This case therefore elucidates a most important fact, namely, that *epilepsy can be produced in a perfectly healthy person* (having no hereditary neuropathic disposition), *by an injury of the head causing commotion without any structural lesion of the brain.*

Although the analogy of our case with the experiments of Westphal is very striking in many particulars, yet there are also apparently some differences. Thus we find a zone in our patient, the mechanical irritation of which calls forth at any moment loss of consciousness with epileptic convulsions, and though this zone is here hyperæsthetic, while it is anæsthetic in the animal, yet during the paroxysms of spontaneous pain it also appears anæsthetic and analgesic. We must bear in mind that we generally judge of the presence of anæsthesia in animals by the absence of expression of pain (screaming); but this was also the case

with the patient, who, though suffering intensely when the painful zone was touched, never manifested any sign of pain, but only became pale and lost consciousness. Possibly animals artificially made epileptic, suffer also from paroxysms of pain similar to those of our patient, but which have escaped our observation. Again, the blindness during the paroxysms of pain (probably a vaso-motor phenomenon) has not been noticed in the experiments on animals. Furthermore, the painful zone in our patient was above the eye, whereas in the animal the epileptogenic zone is situated below the eye. These differences, however, do not seem to be of great importance, and may depend on the incompleteness of the observations, on some unknown anatomical variations, or on differences in the localities to which the traumatic irritations are applied.

Of late, cases of epilepsy have been published, in which an epileptogenic zone has been observed, though in by far the great majority of cases this zone is not present. I treated a patient affected with epilepsy, in 1868, who in several respects resembled the one described in this paper, especially as regards the blindness and headache.[1] I regret not to have paid at that time the necessary attention to the existence of an epileptogenic zone. Subsequently I received additional information from this patient, who is now in perfect health, that in his case there was also great tenderness in the region of the temples, which could not be touched, and that the affection originated from an injury of the head. I may add that, in this case too, the disease, which did not yield to the different remedies employed, nor even to a fortnight's galvanization of the head, was successfully treated by a method similar to the one above described. It seems likely that the cases of epilepsy with an epileptogenic zone are of traumatic origin, and it is therefore advisable in every case of epilepsy to look carefully for an epileptogenic zone. Of course, in the human subject the place of this zone may not always correspond to that observed in animals. It is also probable that in the course of time the epileptogenic zone becomes reduced, and finally disappears, thus escaping further observation.

We are now led to inquire whether, in the majority of youthful epileptics, the disease has not been caused by frequent injuries (falling upon the head), in childhood, especially in individuals with a hereditary neuropathic disposition. From this point of view it would seem surprising that comparatively so few are affected with epilepsy and petit mal. The experiments on animals teach us, however, that not every blow upon the head even in the guinea-pig—this neuropathic animal *par excellence*—is liable to produce epilepsy. For the same reason, in the child, the favorable conditions for producing epilepsy are comparatively rare: it would possibly be requisite to have the head fixed to a solid immovable object, striking it repeatedly with a certain force, and perhaps even at a certain region. If we admit the traumatic origin of epilepsy, we are then enabled to explain satisfactorily many phenomena which accompany this disease, as for instance the prevalence of epilepsy in youth, the hereditary transmission of the disease, the negative results obtained from the pathologico-anatomical investigation of the brain (at least the absence of structural lesions of the brain), the vaso-motor and other phenomena which epilepsy has in common with cerebral commotion, etc. Lastly, I should like to direct the attention of the profession to the above-

[1] Neftel, Galvano-Therapeutics. New York, Appleton, 1871, p. 113.

described method of treatment, which may possibly be also found useful in other cases of epilepsy.

To conclude, I shall sum up what has gone before in two propositions:—

I. It is made evident by the case described, that in a perfectly healthy person, free from any hereditary disposition, epilepsy can be brought on by traumatic influences upon the head, causing cerebral commotion without any structural lesion of the brain.

II. Further investigations will be needed to prove that such traumatic influences during childhood may constitute a most frequent etiological factor in the production of epilepsy.

THE INFLUENCE OF HIGH ALTITUDES ON THE PROGRESS OF PHTHISIS.

BY

CHARLES DENISON, A.M., M.D.,

OF DENVER, COLORADO.

It is assumed that this occasion calls for something suggestive, leading an inquiring mind to look at an important subject in a new light, and seeing the errors of former beliefs through a change in the channels of thought. How desirable then, if we are not now perfect (and I believe the hopeful mind of to-day has more to expect from what we are to learn, than from what we now know), that a controversy of opposing views should here be stimulated in friendly discussion. Believing that our profession as a body is proving itself an insufficient barrier to "the progress of Phthisis," and having convictions which persuade me to differ from many of the authors[1] who have written on the subject of climate and consumption (and I have endeavored to consult them all), I may be excused for seeking to introduce this discussion by occasionally emphasizing these differences of opinion.

The subject assigned me is one of the most interesting and important that can claim our consideration, and all the more so because it has not hitherto received any special attention from our profession at large. As to the disease itself—this great and persistent destroyer of mankind—valuable results have of late accrued from the constant inquiry and pathological research of eminent medical men. Thus this disease has come, through the critical analysis of a transitionary stage in professional opinion, to include, under the one name of Phthisis, various and widely differing abnormal conditions.

Climate and Consumption.

We can define Pulmonary Phthisis as *slow death commencing in the lungs*, or, going back of the local affection to the dyscrasia or abnormal blood state which precedes or accompanies its progress, we can enlighten ourselves as to the various pulmonary and other defects which have till of late been considered as one disease. However, the scope of this report, and lack of time, make the minute consideration of this subject an unwarrantable digression, so that we will content ourselves with the generally accepted significance of the term Phthisis in its broadest sense, including those morbid conditions (chiefly inflammatory[2]) which favor

[1] Dr. Hermann Weber and Dr. Archibald Smith, late of Lima and elevated resorts in the Peruvian Andes, are notable exceptions.

[2] Dr. Hermann Weber, in the Medico-Chirurgical Transactions, vol. lii. (Treatment of Phthisis by Prolonged Residence in Elevated Regions), gives the credit of first promulgating these views to the late Dr. Thomas Addison. "whose teaching, that inflammation constitutes the great instrument of destruction in every form of phthisis, was for a long time either ignored, or regarded as erroneous, by most of his contemporaries." (On the Pa-

weakening or a breaking down of pulmonary tissue; and refer to special phases of the disease as the illustration of our thought may seem to demand.

In considering the climatic treatment of Phthisis, it is not essential to dwell upon the first experiences of our medical fathers in this matter. The conclusion of Dr. Walshe, that "climate takes its occasional share in bringing about the nearest approximations to real cure therapeutically obtainable,"[1] has at length come to be very generally held by medical men. Even before the disease was well understood, while the failure of medicine to cure or check it was slowly being realized, the considerable benefit derived from even mild changes of climate must have strongly suggested a climatic cure. So if the remedy of high altitudes had not long been utilized, as we now learn it has been in the Peruvian Andes, the first two cases mentioned by Dr. Hermann Weber, in his excellent paper "On the Treatment of Phthisis by Prolonged Residence in Elevated Regions,"[2] would have suggested this most potent means of cure to every reflective mind. These cases occurred in natives of elevated localities, who had become residents of London. Prostrated by acute phthisis, they returned to spend the remainder of their probably short lives in their early homes, the one to the Black Forest, in Germany, at an elevation of 2800 feet, and the other to Switzerland, 5000 feet above the sea-level, and in both the disease was quickly arrested. The evidences of the therapeutic value of high altitudes are, however, comparatively recent.

Thus it is not strange that, having no better experience to trust to, the medical profession has hitherto placed confidence in the scattered successes furnished by Mediterranean, low continental, maritime and English health resorts. In England, and on the continent, the description and classification of favored health resorts have been carried to an exactness which has hardly been reached elsewhere.[3] But it is a question, in my mind, if these analyses are not sometimes made to the exclusion of important data, notably the moisture of the air, and with undue importance given to less vital points, such as the precise degree of temperature and the daily variation. Then again the author so often feels it incumbent on himself to tell you how to get away from a place, if you are not suited, that often no relief would seem to be expected; while the poor invalid, usually in some doubt, ekes out a six months' health trip at as many separate resorts. This guessing at the answer to the invalid's conundrum, "where can I best find relief," is far from the certainty and confidence in the course to be pursued, which should characterize the climatic treatment of phthisis. There may be some physicians who are so specially gifted in the adaptation of these low climates to the consumptive's needs as to gain very fair apparent success. After studying the descriptions of numerous low, inland, and seaside Mediterranean health resorts, with all the phases and symptoms of phthisis so nicely met by the appropriate

thology of Phthisis, by T. Addison, M.D., Guy's Hospital Reports. 2d Series, No. V., 1845.) The same has recently been emphasized in the works of Dr. Felix Von Niemeyer, and among others by Dr. Ludwig Buhl (Inflammation of the Lungs, Tuberculosis, and Consumption, New York, 1874).

[1] Diseases of the Lungs. W. H. Walshe, M.D. London, 4th edition, page 585.

[2] Loc. cit.

[3] Climate, in Williams's Pulmonary Consumption; Lettsomian Lectures, on the influence of climate in the treatment of pulmonary consumption, by C. T. Williams, M.D.; Consumption, its early and remedial stages, by Edward Smith, M.D.; Diseases of the Lungs, by Dr. Walshe, 4th edition; The effects of climate on Tuberculous disease, by Edwin Lee, M.R.C.S., one of the Fiske Fund Prize Essays.

climatic remedies, I must confess to a slight feeling of hesitation. It is well for us to ask ourselves how certain we are of any permanent relief being obtained by consumptives in low humid climates. Though there is no lack in the number of "watering places," the field is so small (with elevation left out) that one might almost as well think of supplying all the climatic needs of consumptives within the boundaries of the little State of Massachusetts. If in these low and narrow limits favorable qualities are found, then efficiency in the climatic treatment of phthisis demands more decided proportions of these same qualities, which we hope to show are to be found, together with additional advantages, at suitable elevations.[1]

Low Climates.—As I am going to speak positively in favor of the utility of high altitudes, where not specially contra-indicated, and shall ask you to concur with me in this favorable opinion, it is well to make mention of the grounds I have for feeling less confidence in low climates. As will be apparent when we come to discuss the humidity of the air, we are deprived of important data with regard to the undesirableness of low climates, in that we have few positive records of the relative or absolute humidity of these places in Europe. They all, however, represent more or less moist climates. Of climates in England, Dr. C. T. Williams, in his very carefully prepared Lettsomian Lectures, gives valuable statistics of several localities, mainly along the southern shore of the Island, and remarks upon the favorable results of 386 winters spent at those places by 243 consumptives. "Bear in mind," he says, "that these general results assign the largest amount of benefit to the most easterly stations, and follow a course exactly the reverse to that of the warmth of the localities; Hastings, the coldest, being at the top of the list, and Torquay, the warmest, being at the bottom," Ventnor and Bournemouth being between these. This result will be claimed as an argument for high altitudes, when we come to consider that a cooler temperature, as well as decreasing humidity, are found to be the natural attributes of great elevations.

On the continent, there are also warm, moist climates, called *sedative*, and more exhilarating resorts, termed *stimulating*,[2] which, like Hastings in England, begin to partake of the best qualities of high altitudes, and to show, according to Dr. C. T. Williams's excellent tables, a proportionate improvement for the winters there spent by consumptives. Of the former group there is Pau, remarkable for the *stillness* of its climate, where, as we are informed, a plentiful amount of rain "falls perpendicularly."[3]

[1] In Europe, a reason has seemed to exist for sending south to the warm shores of Italy and to the south of France those consumptives who, from feeble stomachs, are unable to digest the quantity of food necessary to supply the waste caused by the greater amount of oxygen inspired in the colder regions of the north. In the warm, moist climate, less carbonic acid is given off, and less heat required, so that the feeble digestion is not so heavily taxed as in the severe climate of England. The plan works well, chiefly as a palliative measure; but as warm weather comes on it is reasonable to believe that the scales must be turned, and that the indigestion and enervation felt at the South may be much relieved by a return to the cool climate of the North. So the consumptives who have shunned a harsh New England spring, by a sojourn in Florida, hasten back, as warm weather approaches, to cool seaside and country resorts, and are kept constantly on the move, with considerable indifferent benefit. This idea of allowing the digestive capacity to decide to what climate a consumptive should go, may often seem to result in good, but it is founded on uncertain premises, and lacks much desired definiteness in results. Like much of the theorizing as to the treatment of phthisis indulged in by authors for many years, it is not radical enough to answer our needs in the war we have to wage against one of the greatest of human destroyers.

[2] Walshe, op. cit.

[3] C. T. Williams, op. cit.

There is Valencia, in Spain, which Dr. Walshe characterizes as "probably one of the warmest, most humid and depressing spots in continental Europe;" Pisa, a once populous city in Italy, of which the same author says that it has "completely lost its *quondam* prestige as a sanitarium," though, as we fail to notice positive climatic qualities to greatly recommend it, we are surprised with the further assertion that this "changed opinion is the result of sheer medical caprice;" and Venice and Rome, the latter of which Dr. Williams[1] represents to have "had formerly a great repute, though for many years its unfitness as a shelter for invalids has been recognized, and it is now mainly resorted to for pleasure, and not for health." Among the latter group ("stimulating"), we find Hyères, Cannes, San Remo, and Nice (representing the Riviera), Barcelona, Gibraltar, Malaga, Lisbon, and the Mediterranean islands (as Sicily, Sardinia, Malta, and Majorca), which, as before remarked, partake of more favorable qualities, and are notably less moist, than the "sedative" group, or which have some peculiar attributes; thus Dr. Edwin Lee says of Naples, "The frequent variations from dryness to moisture, and from warmth to coldness, promote the disengagement of electricity."[2]

There are marine climates which, being wholly surrounded by salt water, I fancy confer some of the advantages of sea voyages, in that the air is constantly in motion, and the insensible activity of the skin thereby promoted, while the air is always pure and bracing, considering the temperature. So that these may be considered better than the moist climates on the continent of Europe; and yet Dr. Walshe says of Madeira, "much of this promising character turns out to be practically delusive. The damp is so extreme that changes of temperature thermometrically small —of three or four degrees—prove sensationally great; a temperature of 58° indoors, without being actually cold, is disagreeably chilly," etc.[3] The Canary Isles, St. Helena, some of the Mediterranean islands, the Bermudas, Bahamas, West Indies, etc., may also be considered in this group. There are *relatively* very dry climates, as Egypt and Syria, whose enervating quality is the high temperature which would hardly be bearable, were the dryness *absolute*.[4]

Of American climates, we have the characteristic low resorts of moist and sedative Florida; the balsamic regions[5] among the pines in southern Georgia; the dry and alkaline regions of southwestern Texas, in the vicinity of San Antonio; and the exceedingly equable and mild Pacific coast, San Diego, Los Angeles, Santa Barbara, San Luis Obispo, San José, and San Rafael, in California. Because of the great humidity of the atmosphere, these last are much like the warm moist climates in the Mediterranean basin. The favored low resorts in the United States might be much better chosen climatically speaking, but then the attractions have thus far been where the comforts of life are to be found.

[1] Op. cit.

[2] Op. cit.

[3] A sea captain of long experience, who now lives in Denver, for the relief of asthma, tells me he has carried many consumptives to the Sandwich Islands, "*but brought none of them away.*"

[4] In America, in Southwest Arizona, and in the inland portion of Southern California, notably in the vicinities of the Death Valley and Fort Yuma, the winter months only are comfortable, and sometimes hardly that, because of the intense radiation from the sandy plains. At Fort Yuma, Dr. Geo. S. Rose, of the U. S. Army, has informed me that the mean annual rainfall has been for nineteen years only 2.95 inches, while the average annual temperature has been remarkably high—about 75°.

[5] The Pine Forests of Georgia as a Resort for Invalids; by Ezra R. Pulling, M.D. Reprint from N. Y. Med. Journ., Sept. 1871.

Medium Altitudes.—America is blessed with advantageous resorts for cases in which high altitude is not well borne, or rather not permissible. Notably is this true of the *medium altitudes*, though the need of them has yet to be sensibly felt by physicians who guide invalids, before desirable comforts and accommodations will be assured. Among these should be mentioned the Cumberland Table Land, in the mountains of eastern Tennessee, more especially "Walden's Ridge" (elevation about 2000 feet), lately described by the facile pen of Dr. E. M. Wight, of Chattanooga;[1] western North Carolina (Ashville, elevation 2250 feet);[2] southwestern Texas (Fredericksburg, Bœrne, Uralde, and Ft. Clarke, elevation 1500 to 2000 feet, valley of Rio Grande); southern New Mexico (the Mesilla Valley) and western Kansas (elevation 3000 to 4000 feet), the former in winter and the latter in summer being comparatively warm enough to be placed in this group. So also northern Minnesota (St. Paul and Brainard, elevation 1200 feet), because of its cooler temperature and northern situation. In Europe, examples of medium altitudes might be mentioned, as Silesia (Görbersdorf, 1700 feet), Le Mont Dore (3400 feet), Königswarth in Bohemia (2200 feet), Black Forest (2800 feet), Lower Engadine (about 4000 feet), Eaux Bonnes (2450 feet), Cauterets (3254 feet), and Bagnères de Luchon (2060 feet). In Brazil, Dr. Walshe desires to call attention to San Paulo (2300 feet), a short distance inland from the port of Santos. In Mexico, we have Jalapa (4000 feet).[3]

High Altitudes.—Coming now to high altitudes proper, a few places will be mentioned, chiefly those which will serve for our present study, lying in the region of an *altitude of approximate immunity from phthisis*, which we will consider further on. In Europe we have to content ourselves with more unfavorable complications than obtain in the chosen high altitudes of America. The mountains of the Alps present, in the upper Engadine, such resorts as St. Moritz (6100 feet), Samaden (5500 feet), and Davos (5200 feet). They are high enough for their northern latitude, but are burdened with an excess of moisture gathered by the mountains, exposed as they are to the moist Atlantic currents. This is evidenced by Dr. Walshe's citation from Dr. Hewlett,[4] that, at St. Moritz, "in fourteen winter months (seven in 1866–7, and seven in 1867–8) there were only fifteen clear days, while 148 rainy days, and others more than half clear, with their admixture of snow, sleet, and rain, made up the rest."[5] This is considerably at variance with the excellent reputation Dr. L. Vacher gives Davos, for the five cold months ending with March, during which time only the stay of consumptives at this resort is recommended.[6] It is here that the plan, personally investigated by Dr. Vacher (so novel to us who live at the base of the Rocky Mountains, though partly exemplified by the invalid's experiences in Minnesota), is presented. It consists in keeping invalids in the region of continuous snow, until the thawing season in the spring, when they are quickly removed to a lower level. Dr. Vacher gives the number of invalids seeking this resort

as eight, in 1865; 55, in 1870; 220, in 1873; and 400, in 1874; which ratio serves to show the increasing favor which the results of the treatment have warranted, as well as the comparative newness to Europeans of the special efficacy of high altitudes. I shall have many occasions to refer to the experiences furnished by Davos. In Asia, the elevated plateaux in Persia and Armenia, and those adjoining the lofty Himalaya Mountains, together with other elevated inland and dry localities, would seem to furnish excellent climatic combinations, but I have not the necessary data for an account of that vast section.

In America, North and South, the great Rocky Mountain and Andes chains furnish, along and between their variously diverging branches, almost innumerable resorts of any desired elevation or latitude. From the north to the south, in the United States, the great plateaux and elevated basins between the Rocky and the Cascade Range, the Sierra Nevada and the Sierra Madre Mountains, present variations in altitude, temperature, and humidity, which would claim our attention could we now spare the time necessary to study so broad a field. Generally having favorable climatic attributes, with unfavorable distances and local peculiarities, we pass over this vast section to mention the western slope of the Sierra Nevada, in California (vicinity of lakes Donner and Tahoe, in summer), and especially the eastern slope of the Rocky Mountains, in Colorado and New Mexico. (Cheyenne, in Wyoming Territory, 6100 feet; Boulder, Colorado, 5300; Denver, 5200; Idaho Springs, 7540; Colorado Springs, 5980; Manitou, 6200; Pueblo, 4630; Canon City, 5260; Trinidad, 5800. In New Mexico, Santa Fé, 6850; and Albuquerque, 5030.)

It is in Colorado that the Rocky Mountains proper reach their greatest continuous height, many peaks being over 14,000 feet, and present a remarkable width of 100 miles. Interspersed with these lofty peaks are elevated plateaux, or valleys, as North, Middle, and South Parks, 8000 to 10,000 feet; Fairplay, 9800, and San Luis Park (Del Norte), 7000 feet. In Mexico, this vast plateau is continued, being about 1000 miles wide at the north, and nearly 2000 in length, and is called the *Anahuac*. It varies in elevation from 8000 feet on the east, to 4000 feet in some portions of the western, or Pacific, slope (the City of Mexico, 7400; Chihuahua, 4640), and includes most of the *Tierras Frias*, or cool regions. These exceedingly dry, elevated plains, including extensions to the north into New Mexico and Arizona, would claim much more of our interest and study were the habits and lives of their greasy original inhabitants more inviting and congenial to the cultivated American. The loose sand and fine lime dust, together with the rapidly increasing growth of the prickly and inhospitable cactus, as you go south and southwest from central Colorado, may reasonably indicate the undesirableness of much of that southern region.[1] As exceptions to this uninviting region, I note the beautiful and favorably-located southern slope of the mountains, toward the San Juan river, in southwestern Colorado, where lie the Pagosa springs (most wonderful of the hot springs in America); a genial climate and interesting volcanic region near Fort Bayard

[1] Where the cactus grows to the size of trees, as in some parts of New Mexico and Arizona, Lieut. Philip Reid, of the United States army, informs me, are the most uninviting places imaginable for the steady abode of man. Yet here, on the advent of railroads, I predict will be found the extreme climatic remedy which will suit many in winter who are now without much hope anywhere. Such is the fight the invalid will have to make with his destroyer.

(elevation, 6000 ft.); the foot-hills and possible favored resorts in sunny uplands of Chihuahua; and the inviting surroundings of the antique City of Mexico, almost encircled by the lofty Sierras, which inclose beautiful lakes and favored resorts, and send, among other peaks, the Popocatepetl 17,735 feet above the sea, far into the regions of perpetual snow.

The *Cordillera de los Andes*, which has divided in Guatemala, to form the eastern and western boundary of the *Anahuac* in Mexico, extends into South America, to rise still higher just north and south of the equator. Here the Cordilleras, lying close to the Pacific coast, diverge in ranges which inclose elevated valleys or plateaux from less than 8000 to over 12,000 feet in height, while snow-clad peaks like Chimborazo in Ecuador (21,500 feet), and the Sorata and Illimani, in Bolivia (22,400 and 21,250 feet), tower above.[1] In the central portion of Peru the *Montana* consists of a lofty plateau, averaging 12,000 feet in height, which contains many cities and villages, possessing, according to Disturnel, "a fertile soil, amid the most magnificent scenery on the earth's surface," and "enjoying a temperate and delightful climate." The considerable moisture in the air, for such great elevations, as contrasting with the excessively dry regions on and to the north of the Anahuac, may yet indicate valuable discriminations for the thousands who will seek a restoration of their consuming strength in high altitudes.

Analysis of the Attributes of High Altitude Climates.

We have now hurriedly, and somewhat superficially, reviewed the characteristics of low climates, and have geographically indicated medium and high altitudes. In claiming our present consideration, high altitudes have *positive* features and effects to contrast with the *uncertainties* of low levels. Therefore it is to be hoped that the considerable space given to low climates may not be thought amiss: so much does our appreciation of good, as in fact the enjoyment of life, come to us by contrast. I have gladly accepted the invitation to consider high altitudes in general, rather than any one locality, though I fear that the dry study of so large a field will tax your patience, and be otherwise unsatisfactory. Let us then consider high altitudes in the abstract, and seek to analyze the attributes of its atmosphere, leaving, for the present, geographical and local considerations mainly in the background.

We may form in our minds an idea of the climates which will best answer the consumptive's needs. Not that we can fathom the Creator's plans, and improve on the world he has given us, but that having satisfied ourselves of the *ideal*, for the majority of phthisical patients, we may then seek the *real*, among the varied climates of the earth. Here it is instructive to remark how various are the visions indulged in by unsatisfied man, of the most beautiful and desirable country in which to live. It is of consequence also to note that it is improbable that we physicians would agree, were we to vote now as to the average tempera-

[1] When it is considered that, under the equator, the growth of wheat is not established till the altitude of 4500 feet is reached, and that sugar cane has been grown at 7500 and the banana at 5400 feet, it is not to be wondered at that the most comfortable existence for man is to be found at a considerable elevation, and that populous cities lie high up in the mountains, as Bogota, the capital of the United States of Colombia, 8650 feet; Quito, of Ecuador, 9540 feet; Cuzco, the ancient capital of Peru, 11,380 feet; and towns bordering on lake Titicaca, between Bolivia and Peru, 13,000 feet.

ture, humidity, amount of sunshine, electric tension, elevation, and characteristics of wind, as to direction and velocity, etc., of our ideal climate, for the majority of consumptives, or even for uncomplicated phases of the disease. The attributes of climate just mentioned are so intimately interwoven and dependent on each other, that their separate consideration is difficult. We will try, however, to avoid repetition by referring to them in the order named.

Temperature.—The temperature of high altitudes makes life pleasant under the equator, and gives marked variety to climates north and south of that line. In general, the decrease in the temperature of the air has been reckoned at 1° Fahr. for each 300 feet of elevation.[1] But the rule for the decrease of temperature cannot be arbitrary for all elevations, because of local peculiarities. For instance, the mean annual temperatures of places along the eastern base of the Rocky Mountains in Colorado, are much higher than their elevations would indicate, judging from the records of stations in the same latitudes on the Atlantic coast of the United States. The cause of this is (1) *The far inland position.* "The sun's rays passing through the air with but trifling loss, fall on land or on water. The specific heat of land being only one quarter that of water, it both absorbs heat and gives it out more rapidly . . . consequently the more land the greater is the heat, and the wider the diurnal and yearly amplitudes of fluctuation."[2] (2) *The dry sandy soil.* The plains are generally but lightly covered with grass (rivers and trees being very limited), and this tends to increase the difference between ordinary clay soil and water, and so furnishes both greater absorption and greater radiation of heat than the ordinary soil of lowlands. (3) *The protection afforded by the mountains*, to the west and northwest. These break or divert strong winds, and gather moisture from western currents, thus promoting an increase of sunshine on the plains. (4) *The dry and warm Equatorial and Pacific winds.* These prevail at all exposed points on the mountains, and bring pleasant weather to the plains below.

In considering the variations of temperature referred to above, we remark that the more rapid absorption and radiation of heat by land than by water, explains the low fall of temperature at night, and the considerable rise at midday, away from the sea-coast, and shows, by inference, the *equalizing* influence on temperature of moisture in the air. These variations are increased in high altitudes by the lessened capacity of the air to hold moisture, due to elevation and the resulting loss in weight. The annual fluctuations, due to the changed angles with which the sun's rays fall on the earth, are for the same reason affected by elevation. Thus the following table is explained, giving the mean daily range, the average monthly range, the range of monthly means, the annual means, and the annual range of temperatures of places chosen as nearly as possible in the same latitudes, on the sea-coast, inland, and at the base of the Rocky Mountains.

[1] Under the equator it has been estimated to be 1° Fahr., near sea level, for each 333 ft.; for each 297 feet at 10,000 feet, and for each 318 feet at 20,000 feet elevation; while recent observations, in temperate climates, have given the rule of 1° Fahr. for every 400 feet. The records of Mr. Glaisher's balloon ascension indicated different strata of air, the fall in temperature being under a clear sky 5° Fahr. for each of the first four inches of barometric fall, then 4° per inch till the thirteenth inch of descent, and 4.5° each for the last three inches.

Besides showing the effect of inland position and elevation on the daily, monthly, and annual ranges of temperature, this table makes evident certain facts of interest both in reference to the stations separately, and the groups into which they are divided. (1) The fluctuations in temperature (notably, of course, in the annual range) decrease toward the South. This continues till even greatly elevated localities, near the equator, are quite equable in temperature, as on the elevated plains in the Peruvian Andes. (2) The comparatively low range of monthly means, at the "elevated stations," considering the high mean daily, monthly, and annual ranges (with the low average relative humidity of this section, about .45), indicates that there must have been a large proportion of pleasant, even weather at those stations in each month, to have made up for those other extremes. This preponderance of pleasant, sunny weather is quite uniform at the base of the mountains. (3) The extremely low mean range of temperature for all divisions of time, on the Pacific coast, indicates the existence there of a continuous, warm, moist wind, which is unobstructed, and only gives up its moisture when cooled by the winter temperature of that latitude.[2]

The influence of heat on the activity of several functions of the body leads us to prefer a cool to a warm temperature. (1) Heat is opposed to stimulation, so far as the nervous system is concerned. "In experiments

[1] Report of the Chief Signal Officer, War Dept., 1875.

[2] It is unobstructed, for otherwise there would be greater precipitation of moisture, and accompanying thermal changes. That it only rains in winter, is a fact known to all. It is a continuous wind, for otherwise terrestrial radiation and absorption would have produced a much more marked effect on the temperature than the records show. It may be considered warm, because a cold wind could not carry moisture enough to have produced such thermal effects in these latitudes. It is moist, because if it was dry the daily and seasonal influences of the sun would be greater than the records show. We are not surprised then to learn that the average atmospheric humidity is out of proportion to the amount of rainfall on the Pacific coast.

on frogs, when a temperature much over the natural amount is applied to nerves, the electrical currents through them are lessened, and at last stop.[1] E. H. Weber's observations[2] show that for men the same rule holds good, the most favorable temperature being 99.5° Fahr."[3] Then a contrast between the temperature of the surrounding air and that of the body favors the influence of atmospheric electricity, which experience proves to be an active agent at considerable elevations. (2) Heat in the shade has been shown by Rattray[4] and others to have a sensible effect in increasing the temperature of the body, to counteract which a healthy activity of the skin is required, but is impeded by a coincident high relative humidity of the air. The experiment of entering a heated oven (200° to 300°) becomes more difficult when the air is moist than when it is dry; evaporation is hindered, and the bodily temperature is said to rise even 7° or 8°.[5] (3) Heat lessens the number of respirations per minute. According to Rattray's observations, the variation has been known to be from 16.5 respirations per minute in England, in winter, to 12.74 and 13.74 in the tropics. Other observers note that the breathing is also less deep. Dr. Francis (Bengal Army) and Dr. E. A. Parkes[6] have both observed that the lungs are lighter after death in Europeans in India, than the European standard. On the other hand, a healthful activity of the respiratory function is favored by a cold temperature, and is an important feature of the high altitude cure. (4) Heat, especially if continuous, lessens the digestive powers. The stimulation of the appetite which cold is well known to produce, is lacking, especially for much-needed animal food. So the destruction and formation of tissue is retarded. This is also opposed to that renovation of system which is decidedly promoted by both cold and elevation.

Humidity.—To continue our proof that *cool, dry* climates are better constituted for the needs of phthisical patients than those which are *warm* and *moist*, we will consider the humidity of the air, bearing in mind that coolness and dryness are constantly favored by increasing elevation. This brings us to one of the strongest arguments in favor of high altitudes. It is, however, difficult to thoroughly explain this subject, because of our lack of familiarity with the precise laws which govern the various changes of the moisture in the air.

The Signal Service Bureau of the United States Army determines the *relative humidity* of the air by the difference in temperatures given by the wet and dry bulb thermometers, and thus the percentage of saturation of the air is known. But these humidity records have not been well distributed, and it would seem either that the officers of this bureau have little confidence in the reliability of humidity statistics, or that they do not appreciate their important bearings on scientific and climatological investigation. While the *relative* amount of atmospheric moisture is most important, as determining the healthful activity of the skin, the evaporation and quickening of perspiration from the surface of the

[4] On the Effects of Change of Climate on the Human Economy, by A. Rattray, M.D., Surgeon R. N. Proceedings of the Royal Society, 1869–1872.

[5] By inference we find here one cause of sunstroke, which in our experience does not occur at great elevations in America, notwithstanding that Dr. Vacher (op. cit.) speaks of sunstroke occurring on the Alps.

[6] On Algide Cholera, by E. A. Parkes, M.D., p. 14 (1847).

body being greatly in proportion to the removal of the dew-point and temperature of the air from that of the body, yet these records are in a measure superficial, simply because they are *relative* and not *real*. This, too, notwithstanding that a little more than half the ratio of saturation is shown by them on the plains east of the Rocky Mountains, to that which exists in some localities on the sea-coast. This is proof enough that our temperature is not much in the suspicious company of the dew-point. I am, however, inclined to claim that the importance of a large amount of atmospheric vapor, as a causative, and of a small amount, as a curative, element of phthisis, is such that the *absolute* rather than the *relative* amount of moisture in the air needs our special study. If to-day we were possessed of the knowledge of the average amount of vapor in a cubic foot of air in all parts of the country, I believe we would have one, if not the most valuable indication possible, of the best localities for phthisical patients. With some reservation as to temperature, the smallest ratios would indicate where consumption originates with the greatest difficulty, where a low ratio of relative humidity, a small annual rain-fall (excepting sudden and great precipitation), a large proportion of sunshine, and a favorable diathermancy of the air would be assured, so much do these favorable conditions accompany real dryness of the air. This absolute humidity would of course be shown to be greatest in the tropics, least toward the poles; increased over large bodies of water, decreased as we go inland from the sea; increased by heat, as in summer and at mid-day, and decreased by low temperature, as in winter and in the morning.

To more fully consider the importance of the real atmospheric humidity, it is to be noted that the air is capable of holding moisture, mainly according to its temperature. The expansion of air under the influence of heat increases its capacity for retaining invisible vapor from about half a grain in a cubic foot, the limit at zero, with a barometrical pressure of thirty inches, to 19.84 grains, the limit at 100° Fahr. (See Table II.) As to a loss due to change in the weight of the air, many complications present themselves, among which a very slight one is the fact that dry air weighs from 2 grains at a temperature of 44° Fahr., to 8 grains at 80° Fahr., more in the cubic foot than saturated air.[1] The elastic force of vapor, or the absolute humidity of the atmosphere, Mr. Buchan says, "diminishes with the height, but the average rate at which it diminishes is not known."[2] The records of balloon ascensions give some information in this direction, but not sufficient to constitute any rule of change. The balloonist Croce-Spinelli, who perished in his aerial flight, recorded before he died that, at an elevation of 16,370 feet, "there was no longer vapor in the air." And the experience of many of us who have ascended great heights, agrees with that of Gay-Lussac, who recorded in his balloon ascension that, at 14,715 feet, "the air was so dry that for want of saliva he could hardly swallow bread." We understand that the air is twice rarefied at a height of 3½ miles, 4 times at 7 miles, 16 times at 14 miles, 64 times at 21 miles elevation, etc. This expansion of the air with increasing elevation is accompanied with a loss of part of its humid contents, through the coincident cooling which takes place, so plainly described by Prof. Tyndall.[3] If, with our "mind's

[1] Smithsonian Meteorological and Physical Tables, by A. Guyot.
[2] Handbook of Meteorology, by Alexander Buchan, 2d ed., p. 162.
[3] The Forms of Water, by John Tyndall, LL.D., F.R.S., 1874.

eye," we follow a cubic foot of saturated air in its ascent through space, we notice the loss of most of its moisture through the chilling due to the expansion; but there is another portion of the moisture, as well as of the air, crowded outside the cube by the same expansion. Mr. Glaisher's tables, before referred to, which give the weight of vapor in a cubic foot of saturated air at different temperatures, are made for a barometric pressure of 30 inches. If these tables are as accurate for places a mile up in the air as for those at sea level, then there is no diminution of moisture due to elevation independent of temperature, and the saturated air of such height may retain more moisture in proportion to its weight for a given temperature than the air at sea level. The air at the School of Mines, in Golden, Colorado, 5900 feet above sea level, was found by Prof. E. J. Mallett to contain at 60° Fahr. 331 grains of nitrogen and 99 grains of oxygen, or 430 grains weight for the cubic foot, which is just about four-fifths the weight of air at sea level.

TABLE II.—*Showing Weight of Vapor, in grains Troy, contained in a cubic foot of saturated air, at temperatures between* 0° *and* 105° *Fahrenheit.*[1]

33	2.208	60	5.756	87	13.546		

Is there no diminution in the capacity of this rarefied air for moisture, due to this lessened pressure of three pounds to the square inch? The question is of importance to us as affecting the basis of our judgment of high altitudes. Besides, the Signal Service weather reports often come to us with relative humidity noted as "not corrected for elevation," and we are left to learn what such correction may be. Now, seeking to avoid the headache and uncertainty which are induced by the search for suitable explanations in Guyot's and Glaisher's complicated tables, we will simply say that the only correction given is by the former author,[2] and adds from two to three per cent. to the relative humidity of places of the altitude of the Rocky Mountain base. This correction, as affecting the dryness of air in high altitudes, amounts to but little; besides, as before inferred, the comparison of climates by the *relative humidity* of each, is superficial, when temperature is not taken into account. With temperature, however, as indicating the capacity for moisture, the question becomes equivalent to this: Is the comparison of climates by the *absolute humidity* of each just? Our argument in advance has been that possibly it is unjust to high altitudes, as far as desirable dryness is concerned. Let us suppose it just, however, and (adding Guyot's corrections) make one or two comparisons which will suffice for all, and show the superiority of the highlands over the lowlands. We are enabled to compute the weight of vapor from Mr. Glaisher's table already given, or from one of Guyot's tables. Compare Jacksonville, Florida, with Denver, Colorado.

[1] Smithsonian Meteorological and Physical Tables, page 93.
[2] Ibid., page 72.

According to Dr. Baldwin,[1] the mean annual temperature of Jacksonville is 69.82° Fahr., and the mean relative humidity .696. The Signal Service records at Denver give a mean annual temperature of 49.2°; relative humidity .46 (corrected for elevation, .48). Then the average cubic foot of air in Jacksonville contains 5.6 grains of vapor, while in Denver the amount is 1.91 grains, about one-third as much. Or again, to compare the humidity of Jacksonville, Davos, and Denver, for the five cold months ending with March, the term of the thermal cure at Davos, we have:—

	Mean temperature.	Mean relative humidity.	Grains of vapor in a cubic foot.
Jacksonville	60°	68	3.92
Davos	23	84[2]	1.24
Denver	33	51[2]	1.13

The small amount of absolute humidity compared with the high relative humidity of Davos, shows the fallacy of judging solely by the relative humidity, while the whole table shows the remarkable dryness of high altitudes in winter.

The sensational effect of cold with excessive *absolute*, as opposed to a high ratio of *relative*, humidity, and really little moisture, is considerable. A gentleman, now a resident of Denver, who formerly resided in Jacksonville, says that he "stands the winter cold better," and "feels less chilly," in Colorado than in Florida; and the temperature of 58° Fahr., in doors (which is always very comfortable in Denver), is said by Prof. Walshe to be "disagreeably chilly" at Madeira. Excepting certain high altitudes where mountains act as constant condensers of moist currents, it is now incontestably shown that, as to temperature and humidity, coolness and dryness are progressively concomitants of increasing elevations. The proof that cool, dry climates, or high altitudes, are better than warm, moist ones, or tropical lowlands, needs no better conclusion than the evidence furnished by Dr. C. T. Williams's excellent analysis of 593 winters spent by 251 consumptive patients in foreign climates. I quote with pleasure (and with thanks for the unintentional favor) the indisputable evidence which this zealous student of European and lowland resorts gives for high altitudes.[3] I have already adverted to the experience of 243 consumptives who spent 386 winters in English "home" stations, which resulted in the colder resorts carrying off the palm.[4] Now as to the experience in foreign climates, Dr. Williams concludes: "As to what class of patients profit most by dry climates, it has been shown that, taking collectively all forms and degrees of phthisis, the dry climates are the most likely to arrest the disease. . . . As to the desirability of moist climates for consumptive patients, the evidence is decidedly against their use in the treatment of ordinary chronic phthisis. The addition of warmth only makes the damp tell more unfavorably, though a strong saline element and invigorating breezes do something to counteract the humid influence. Still even these do not place a moist climate on the same level as a dry one."

Diathermancy of the Air.—A striking, and to most people a novel feature of high altitudes, is the clearness of the air, as shown by the intensity of the sunshine. I was impressed with this characteristic of Colorado

[1] "An address on the Climatology of Florida." By A. S. Baldwin, M.D., President. Proceedings of the Florida Medical Association, Sessions 1874 and 1875.
[2] Corrected for barometrical heights by Guyot's Meteorological Tables, 3d ed. page 72.
[3] Lettsomian Lectures, Lecture III. [4] Id. op., Lecture II.

air on my first arrival three years ago, when, while riding toward the northeast, on a cold winter afternoon, the exposed portions of my body became chilled, while the back of the carriage seat, on which the sun was shining, was very hot; and I have ever since been curious to understand the phenomenon. After ineffectually endeavoring to get the Signal Service officers to study this matter, I conceived the idea of determining for myself the ratio of difference between the temperature in sunshine and shade, for each decided elevation, believing that, with the same conditions, excluding the influence of the wind, artificial heat, etc., observations at a few stations would serve to establish an approximate rule for almost all elevations. Accordingly, since February last, the desired temperature has been recorded at Washington, D. C.; at Royalton, Vt.; at Denver; and more lately by C. S. Richardson, C.M.E., at the Dolly Varden mine, on Mt. Bross, Colorado. Ordinary thermometers in metallic frames, and of Fahrenheit scale, have been used, observations having been taken at 2 P. M., on clear days only; and western rooms, not artificially heated, and with western windows, having been chosen. The temperature of the room has been taken in the shade and sun, with the window closed, and also with the window open, the direction, etc. of the wind being noted. The results must be taken as only approximate for general conclusions, because of the many conditions by which they may be affected, the fewness of the stations, and the short time the observations have been continued, extending only over parts of March, April, May, and June.[1] I have lately found an average of the same kind as my own, taken at the city of Mexico by Dr. Jourdanet,[2] which I add to the accompanying table:—

TABLES III. AND IV.—*Showing Diathermancy of the Air.*

STATIONS.	Elevation above sea.[3]	Difference between temperature in sun and shade in-doors, window shut; from	Average difference.	Ditto, window open or out-doors, the windy days excluded; from	Average difference.
Washington, D. C. . .	80 feet.	12° to 37°	23°	17° to 37°	24°
Royalton, Vt. . . .	500 "	16 to 42	27	23 to 47	28
Denver, Col.	5200 "	40 to 48	43	46 to 55	50½
Mexico, Mex. . . .	7600 "	....	...	56 to 65	60[4]

STATIONS.	Elevation above sea.	Temperature in shade.	Temperature in closed box with glass cover (sunshine).	Difference.
Mt. Bross, Col.	13,400 feet.	56°	162°	106°
Alma, Col.	8,800 "	68	154	86
Denver, Col.	5,200 "	88	160	72

Besides the increase of diathermancy, the tables show the more uniform clearness of the air at high than at low altitudes. From these

[1] Lately I have been pleased to learn, from Dr. Vacher's brochure on "Davos, Le Mont Dore," that others also have been making observations similar to my own. But as these observations, one with the thermometer in vacuo, and another, that of M. Saussure, which consisted in "exposing to the rays of the sun a thermometer placed in a wooden box lined with black cloth, and covered with glass," were not made under conditions favorable and usual to human existence, I have more confidence in the utility of my own; though the contrasts between sunshine and shade are not as great in my observations as in the others.

[3] Partly from Dictionary of Elevations and Climatic Register. By J. M. Toner, M.D., 1874.

[4] Taken in January.

tables we can approximately arrive at the desired result, the difference between sunshine and shade, or the heating power of the sun's rays. Mr. Richardson has kindly taken many observations for me on Mt. Bross, the difference between the temperature in the sun and in the shade out-doors at 2 P. M. being only from 10° to 20°, and not showing the real diathermancy of the air. This I attribute to the rapid radiation of heat and constantly moving cold air of that exposed place. As there was no suitable building in which to try the other test, I prepared pasteboard boxes, with glass covers, and with black velvet lining, in which we took the temperatures at Denver, Alma, and on Mt. Bross, at 2 P. M. for a few days, at nearly the same season. The differences between these records and the temperatures in the shade, noted at the same time, serve to show the increasing diathermancy of the air at these greater elevations, notwithstanding the peculiar influence of the cold air and wind of those heights. Now the differences between these diathermancy tests tally as follows for the given differences in elevation:—

TABLE V.

Stations.	Difference in elevation.	Average difference in diathermancy.	Average difference in elevation for one degree of diathermancy.
Washington and Denver	5120 feet.	23°	223 feet.
Washington and City of Mexico . . .	7520 "	36	209 "
Royalton and Denver	4700 "	20	235 "
Royalton and City of Mexico	7100 "	32	222 "
Denver and City of Mexico	1400 "	9½	148 "
Denver and Mt. Bross	8200 "	34	241 "
Denver and Alma	3600 "	14	257 "
Alma and Mt. Bross	4700 "	20	235 "
		Average . . .	221 feet.

Thus is evolved a general rule, which may be changed by more accurate and extended observations, of *one degree greater difference between the temperatures in sun and shade, for each rise of about* 220 *feet.*

This diathermancy (the increased facility with which radiant heat is transmitted) explains as clearly as the absolute humidity of the air, the daily fluctuations in temperature so gradually augmented with increasing elevation. But the absolute humidity, or elastic force of vapor in the air, is the main key to its transparency, the elevation only giving an additional increase in diathermancy to that produced by the decreasing humidity. So dry, low places, like Fort Yuma, California, will be exceptions to the rule given. However, this does not disprove, but, on the contrary, helps to establish the increased diathermancy of high altitudes, where, as we have already shown, there exists a considerably lessened absolute humidity. The effect of this diathermancy of high altitudes on solar and terrestrial radiation is wonderful. The solar radiation is rapid, and soon after sunrise the temperature rises, because of the slight resistance which the rarefied and dry air offers to the sun's rays; while, after sunset, the terrestrial radiation is also rapid, because there is no moist envelope shrouding the face of the earth to prevent the natural cooling of the dry ground.[1] The climax of this proof is as follows: Reasoning from the effects inimical to life in mines, cellars, and ill-lighted abodes,

[1] The character of the sunlight of high altitudes is a nearer approach, if possible, to white light, than at sea level, and many find it desirable to wear gray-blue or smoked glasses to neutralize its effect.

to the benefits of sunlight at low levels, where a stratum of moisture intercepts the sun's rays like a thin cloud, and thence to the healthful influence of the unobstructed sunshine of the highlands, we can say, without fear of successful contradiction, that the beneficial effects of sunshine increase with increasing altitude. It is further to be noted that, the sun's rays being less obstructed, there is a proportionately *longer* influence of sunshine in each twenty-four hours, besides the excess due to a usually cloudless sky over such plains as those east of the Rocky Mountains.[1] Thus, too, is explained a certain degree of incorrectness of ordinary temperature records of the Signal Service, which are taken in the shade and on the north side of the building, with the cold nine o'clock observation doubled to make up the general average. We are warmer during the hours in which being out of doors is desirable, on the elevated western plains, than is indicated by the temperature records.

Atmospheric Electricity.—The importance of atmospheric electricity as a curative power in disease is not to be measured by the little we know about the element itself. The experience in high altitudes of persons of susceptible nervous temperament goes to substantiate the universal evidence of science that, as a rule, electric tension in the atmosphere is increased with each decided elevation. Leaving out of consideration the change in electric tension and the negative quality of atmospheric electricity during storms, we learn from extended observations (Kew observatory) that with a clear sky the electricity of the air is always positive, which quality, Alexander Buchan says, becomes manifest "on flat ground" at a height of five feet. It would seem that, with the increase of tension due to elevation, the positive electricity of the air, so abundant in dry elevated regions, would be constantly nearing the negative electricity of the earth. With no other evidence to prove this than the experiences of our nervous systems, I shall claim that this is the true state of electric tension of high altitudes, till evidence is produced to the contrary. Now here is important teaching for the consumptive multitude, in fact for most of the human family. The houses we live in, and the piazzas and trees we sit under, are intercepting this vital fluid, which it is very probable we were intended to utilize more than we do. The conception and realization of this truth make us pine for the nomadic life of the travelling Israelites and Arabians, because we are sick at heart in view of the fact of increasing deaths from consumption with increasing civilization.

High-altitude experience goes towards strengthening the common-sense idea of the consumptive's course everywhere, which is in favor of an *out-door life*. The continued mediumship of the human body between the *negative* ground and the *positive* air, whether a man is on foot or on horseback, is a constant renewal of his vitality. Here is a secret of the great utility of camping out and "roughing it" in dry, elevated countries. You lie down to sleep, as only a tired camper-out can, on the ground, and get up in the morning from your *negative electric* bed to stretch yourself in the *positive electric* air. I have yet to meet with the experience which will dissuade me from always giving the advice to consumptives to live in the open air and sleep on the ground, whenever conditions are favorable for so doing.

[1] According to records in the Signal Service office at Denver, there have been only thirteen days since January 1, 1873 (to August, 1876), in which the sun has been invisible the whole day.

Dr. James Henry Bennet, whose personal experience with phthisical invalids entitles his opinion to great consideration, thus emphasizes the importance of defective vital or nervous power as a cause of pulmonary consumption, which cause even underlies "the most minute anatomical and histological researches." "Clinical observation shows that the manifestation of these forms of lung disease, chronic and acute, must be looked upon as the evidence and result of a serious, perhaps final, diminution of vital or nervous energy. . . . . Unless the vitality of the individual can be roused, the morbid condition will surely progress, and life will be extinguished sooner or later, according to the state of the constitution of the patient, and to the type of the disease."[1] Without delaying to add much corroborative proof at hand of the soundness of this conclusion (more especially the influence of inheritance), we can immediately draw the inference, which is abundantly substantiated by experience, that the increased electrical influence of high-altitude atmosphere is one of our most important aids in the successful battle against consumption.[2]

Ozone.—As to ozone, reliable deductions cannot be drawn from experiments made, because of the many liabilities to error with Schönbein's test, which was used—the starch and iodide of potassium paper—and especially one element of error which is liable to be increased in high altitudes, namely, the decided dryness of the air. But from the tests which I have had made on the western plains and in the mountains, the usual increase of ozone in the mountains is shown, while on the plains there is a good proportion, considering the lack of moisture and distance from the sea. A variation in the amounts observed may, I think, serve as a profitable indication of the special advantage of living in the mountains during the heat of summer. It is this, that the excess noted during the spring months on the plains, came proportionately later in the season the higher up the observations were made. This utility of going into the still higher regions in summer is in consonance with the increased benefit of the cooler temperature which we have already shown elevation insures.

Winds.—While not much can be said of the winds of high altitudes, independent of local peculiarities, yet two general facts may be mentioned, which will not be considered detrimental to elevated climates in view of the generally admitted healthful influence of a moderate amount of wind. The total movement of the air at nearly all exposed high altitudes, is of course greater than that at similar places in the lowlands, yet not nearly so much greater for many points as would generally be expected. As I have elsewhere explained,[3] the total movement of air,[4] and the number of observations of wind direction, as to winds which are usually mild and bring pleasant weather,[5] for some elevated stations as at Denver, Colorado, compare most favorably, for mildness of results, with the records of low altitude stations. The winds of high altitudes being less diverted from their general course, their indication as to the

[1] Pulmonary Consumption. By James Henry Bennet, M.D., 2d ed., p. 16.

[2] Some further remarks by the author on this subject may be found in The Archives of Electrology and Neurology, for November, 1874. "The Influence of the Climate of Colorado on the Nervous System."

[3] "The Winds of Colorado." Report to the Colorado State Medical Society, 1876.

[5] Annual Reports of the Chief Signal Officer, U. S. A.

character of weather is more constant than at most low stations, and especially is this the case of inland localities. For instance, according to excellent charts, in the Annual Report of the Signal Service Bureau for 1876, giving wind directions which are most, and those which are least likely to be followed by rain, the indications are very strong for Northern and Eastern Colorado, and Southeastern Wyoming (Denver and Cheyenne), that the south, southwest, and west winds bring pleasant weather, while their opposites, the north, northeast, and east, bring most of the rainy weather.[1] In Eastern New Mexico (Santa Fé), nearly the opposite rule holds good; the northwest, north, and northeast winds bringing pleasant weather, while the southeast, south, and southwest winds bring most of the rain. The damp atmosphere comes in both cases from below—the Missouri valley and the Gulf of Mexico—while the dry, warm air comes from over the mountains, which have acted as condensers. This is proved by the records of the Pike's Peak station, where the rain-bearing winds are the above-mentioned dry winds on the plains, and the pleasant weather winds are the rainy winds on the plains.[2] Another point is that winds of high altitudes, while they have the same influence in purifying the air, have proportionately less force, rapidity being the same, according to the lessened weight of the air due to elevation. It is to be mentioned, however, that in desirable dry regions, as the Eastern Rocky Mountain slope, and especially where the adobe soil of New Mexico, Southern Colorado, and Western Texas, exists, the dust storms which strong winds raise are a disagreeable element, to be avoided for the time being by those having weak or diseased lungs.

Altitude.—The physiological effects of high altitude on man are well understood when we consider the lessened pressure of the air which obtains at a given elevation. Reckoning the superficial area of a man's body as sixteen square feet, and the pressure to the square inch as three pounds less at the base of the Rocky Mountains (6000 feet), than at sea level, we have this surface relieved of the enormous weight of nearly 7000 pounds. With these figures in our minds, we are struck with the wonderful adaptability of the normal human organism to changes in atmospheric pressure, when the limit of danger lies in an atmosphere almost twice rarefied on the one hand, and five times condensed on the other.[3] But when we go further, and learn that Lieberkühn[4] has computed the area of respiratory surface in both lungs of man to be 1400 square feet, which Dalton avers is not exaggerated,[5] we find a subtraction of pressure from those organs which is truly wonderful, even for an elevation of one mile. The respiratory organs, then, are those which are chiefly influenced by the lessened atmospheric pressure, the effect on other organs being mainly secondary to the induced activity of respiration. Let us analyze the *modus operandi* of this phenomenon. The proportions of oxygen, nitrogen and carbonic acid, to each other, do not vary greatly for habitable elevations. There is then a fifth less oxygen in a given

[1] See tables of winds in "The Winds of Colorado," just mentioned.

[2] This evidence seems to be opposed to an explanation of sudden changes in temperature in New Mexico, given by Dr. Gardner as "depending on whether the wind blows from the dry, parched plains of Texas, or from the snow-crowned summits of the Rocky Mountains." "Diseases peculiar to Mountainous Regions." By W. H. Gardner, M.D., U. S. A., Post-Surgeon, Ft. Union, N. M. (Am. Journ. of Med. Sciences, July, 1876).

space of air a fifth rarefied, as at 6000 feet, and the lungs must inspire a fifth more air to get the same amount of oxygen. This is favored, first, by quickened respiration, which as well as the coincident increased activity of the heart is best shown in aeronauts, who make no muscular exertion as they rise.[1] Dr. Vacher says that M. Gaston Tessandier, the surviving aeronaut on the Zenith, gave him the record of his respirations as 26, at 5300 metres (17,331 feet), and on earth 19 to 23 per minute. Dr. Vacher himself, when he went to investigate the wondrous effect of the winter air cure (Cures d'air), at Davos, made careful estimates of his respirations, which were 18.2 per minute at Davos, while at Paris they were 16.6, his pulse increasing from 69 to 78 beats per minute.[2] As I came to Colorado three years ago, I noted an increase in my respirations from 20 to 30 per minute, in 24 hours, while rising 4000 feet in Western Kansas, and an increase of the pulsations from 72 to 82.[3]

I thought I noticed another of the immediate effects of elevation, which I have nowhere seen mentioned, but which may yet be of account in studying the therapeutics of the high-altitude cure of phthisis, an early and almost constant symptom of which disease is *prolonged expiration*. I refer to a quicker expiration, which was as though the increased number of respirations per minute was made up from the time given to expiration.[4] As to the effect of altitude on breathing, Dr. Vacher takes issue with Dr. Spangler, of Davos, and also with Dr. Jourdanet, formerly of the city of Mexico, the two latter gentlemen claiming that "the lungs supply a deficiency of oxygen by deeper and slower," while the former emphasizes the "more frequent" respirations. I shall have to differ with these gentlemen on both sides—especially with Jourdanet—saying the respirations are both deeper and more frequent, at first the *frequence*, and afterward the *profundity*, predominating. According to Coindet, who made 1500 observations of the frequence of respirations in French and Mexicans, they were 19.36 per minute for the French, and 20.30 for the Mexicans. The greater depth and breadth of the lungs of inhabitants of high altitudes has been noted by all observers who have had favorable opportunities for testing the question. Our knowledge of the mountain Indians of the western part of the United States, tallies with the fact noted by Jourdanet, "that the Mexican Indians, though of medium height, have unusually large and wide chests, quite out of proportion to their size." Even children, born in the Rocky Mountains, have been noticed while yet young to have chests of unusually large capacity, and the increased circumference of the chests of consumptives after undergoing the high-altitude treatment, is shown in many of Prof. Weber's cases, as well as in my own. M. Jaccound, at Saint Moritz, says there are not only more frequent, but fuller respirations. "This circumstance brings

Biot and Gay-Lussac, at	9,000 feet,	increase of	18 to 30	beats of the pulse.
Glaisher, at	17,000 feet,	"	10 to 24	" "
Glaisher, at	24,000 feet,	"	24 to 31	" "

[2] Op. cit.

[3] This record is of use, as compared with that of Dr. Vacher, who was probably in health, to show the increased disturbance elevation favors in those whose lungs are impaired; for at that time, ten months after pulmonary hemorrhages, my right apex and some other peripheral lung tissue showed signs of being clogged with inflammatory or other products, since happily driven away by Colorado's light air.

[4] Colorado as a winter resort for invalids. Chicago Med. Examiner, Jan. 15, 1874.

into use certain portions of the lung I call idle, because in ordinary conditions they take only a small part in respiration."[1]

The exercise of the will makes a great difference in the frequency of respiration, and besides, I think, the respirations in high altitudes are more generally increased in frequency by muscular exertion than in low countries, as any member of an Alpine club can testify. Lungs of habituated capacity to high altitudes have little incentive to frequent respiration when perfectly quiet, as is usual when the respirations are counted. Dr. Jourdanet evidently expresses this opinion in furtherance of his theory (Désoxygénation de l'air),[2] that the deficient oxygen inspired at great elevations is the cause of the immunity from phthisis. Now as to both fact and theory I have to differ with this noted author, in reference to the rationale of high-altitude therapeutics. So I may be excused for quoting and commenting at length on his views as given in his "Le Mexique et l'Amérique Tropicale," page 295. "We have stated that anæmia is the habitual condition of men who people great elevations, anæmia by the imperfection of the respiratory act. If it is natural to admit, *à priori*, that this anomaly may have a necessary influence upon the beginning, nature, and progress of maladies in general, with how much more reason must we acknowledge that the organ which presides over the respiratory functions would feel the first influence of it? The lungs in fact find themselves in the presence of a rarefied air, dry, and of diminished barometrical pressure. The three conditions of rarefaction, dryness and lightness of the atmosphere, evidently render the endosmose of oxygen, destined to feed respiration, less easy. But if we are correct in saying that the most natural stimulant of any organ is the element in which it acts, we may affirm, without fear of contradiction, that the lungs are always stimulated in a less degree upon the heights than at the level of the sea." After clearly showing evidences of considerable immunity from phthisis on the Anahuac, and at other elevated stations, he continues: "Moved by the consoling spectacle of this happy influence of great elevations upon consumptives, I have sought a reason for it with the view of turning this fact to a practical account. Several elements are grouped in my mind, in the resolution of this difficult problem. Upon one hand I am governed by an incontestable fact, already proclaimed as a general fact throughout this work; it is that the chronicity of inflammatory affections is incompatible with the climate of the heights. On the other hand, I consider the rarefaction, lightness, and dryness of the air. The rest which results from these conditions excludes the idea of any permanent excitation of the lungs. I consider that, in these circumstances, the lungs find a guarantee against pulmonary phthisis, while upon the coast, in a heavy and humid atmosphere, which oxidizes everything with which it comes in contact, a general predisposition to a chronic inflammatory condition favors the progress of tuberculization. My mind is struck by the importance of these curious facts, from which it draws the irresistible inference that an inflammatory element is necessary to pulmonary tubercles, to follow out the divers phases of their existence, etc."

Let us briefly dissect these anomalous theories, without objecting to the ultimate facts they are intended to explain. This "respiratory diet," as Jourdanet calls it—the theory which makes a deficient supply and

[1] La Station de Saint Moritz, p. 34.
[2] Dr. Vacher's Davos, Le Mont Dore, page 13.

lessened inspiration of oxygen the cause of the immunity of high altitudes—takes no cognizance whatever of the adaptability of the respiratory function to changes in elevation. The bare mathematics by which we get this deficit for high altitudes, which Dr. Vacher reckons is "a daily deficiency of 139 grammes" of oxygen for an ordinary person at Davos, throws out of consideration the existence of a pneumogastric nerve with its reflex function to supply any lack of air, or oxygen its vital constituent. Even if the deficiency of oxygen is not compensated for by more frequent and deeper respirations, it is not proved that endosmose of oxygen has any constant relation to the amount of oxygen inspired. On the contrary, Dr. Parkes says,[1] "in experiments on animals, as long as the percentage of oxygen did not sink below a certain point (14 per cent.), as much was absorbed into the blood as when the oxygen was in a natural proportion." This, too, is in addition to any augmented respiration due to elevation. It is much more probable, in view of the more perfect combustion (oxygenation) which takes place in consumptives who move to the highlands, that this deficiency is more than compensated for in high altitudes. As to the "*anœmia* by the imperfection of the respiratory act" which "is the habitual condition of men who people great elevations" (and so opposed to inflammation), I wish to ask, in all candor, how long are we to continue the manufacture, in our own minds, if not by drugs, of one disease to cure another? What, we are inclined to exclaim, have the much vaunted theories of allopathy (antipathy?) and homœopathy to do with this question? Is the improved and more active circulation of blood in the lungs (even more in them than in the capillary circulation in other parts of the body), a condition of "*anœmia*" on the heights? By no means; it is simply a condition of increased normal activity.

Let us examine this interesting point further, especially noting the changes in density of the respired air, while it is in the lungs. I have already adverted to the wonderful extent of respiratory surface in the lungs. This large area and the considerable change in atmospheric pressure are two striking factors of the changed respiration due to elevation. The mechanical effect of this lessened atmospheric pressure is what chiefly interests us. With the atmosphere say one-fifth rarefied, the respirations are deeper and more frequent. Then the density of the air in the lungs during inspiration would seem to be lessened in proportion to the greater quantity of air which has to be breathed. This increased approach to a state of vacuum in the lungs is calculated to draw the blood quickly into the pulmonary vessels. But expiration follows, and it is during expiration that the respiratory muscles have the greater power, greater because the muscles of expiration are in their normal condition for activity when the thorax is distended, and the thorax is more distended, because it has to labor with more air. I have already expressed the opinion that expiration rather than inspiration is shortened by the diminished pressure of elevation, and this fact would still further show the increased advantage of the expiratory muscles. Then the density of the air within the lungs is suddenly made greater than the density of that outside the body. The bloodvessels are pressed upon, and the previously augmented flow into the lungs is driven quickly on to the left side of the heart. It is possible that in very great changes of elevation, as in quickly climbing mountains above 12,000 feet, or rising to an immense height in a balloon, the pul-

[1] Practical Hygiene, page 407.

monary vessels may not stand this alternate rarefaction and pressure, and hemorrhage may result. But we are speaking now of reasonably high altitudes, which must be considered as varying for different invalids. The more rapid and perfect renewal of the capillary circulation in the lungs is opposed to the stasis of blood which is an early stage of inflammation. Not only that, but chronic hypertrophied tissue, accumulations of mucus, epithelial débris, and the products of inflammation, are "crowded to the wall" by this pressure, increased from within outward during expiration, and the lung thus purified and cleansed of the results of inflammation and morbid products in the blood, of lingering tendency, has no place for adventitious products or the deposit of tubercle.[1] Is this exaggerated activity of the pulmonary vessels and tissue a condition of "anæmia," and is it here we find the "rest" which "excludes the idea of any permanent excitation of the lungs?" "There is no rest for the weary" lung, and in this lies its salvation. Rest is best for a broken bone, but it offers no special antagonism to progressive degeneration of lung tissue, even if, as is here erroneously assumed, "the lungs are always stimulated in a less degree upon the heights than at the level of the sea."

As to the "endosmose of oxygen" being "less easy" in high altitudes, how, may I ask, if it is so, can the lungs enjoy the "rest" claimed, whose function it is to promote the endosmose of oxygen? Is it natural for an organ to be at rest, whose function is obstructed? I can see no obstacle to the endosmose of oxygen due to lessened atmospheric pressure; on the contrary, almost every effect of rarefaction of the air is to complete and perfect this process. According to Dunglison, "the rapidity with which endosmose is accomplished varies according to the nature of the septum or tissue, and of the penetrating body, and to the penetrability of the tissue." Now, in high altitudes, the improved condition of the capillary circulation, everywhere shown, but chiefly in the lungs, the quickened flow of blood on one side of the intercepting membrane, and the proportionately increased pressure and rapid renewal of the air on the other, all combine to favor the endosmose of oxygen. It is not then necessary for us to burden our minds with doubtful problems to understand the healthful influence of the atmosphere of high altitudes upon the organs of respiration. This more perfect oxygenation and capillary circulation of the blood favors a healthy renewal of tissue, and is constantly washing out of the system and preventing the focusing of impurities or disease germs, of which the consumptive body is full.[2]

The improved respiration and circulation bring demands for increased digestion and alimentation. Not only the lungs and heart, but the stomach, liver, and kidneys all contribute a share of this increased labor

[1] Elsewhere I have given the opinion, which I have never seen mentioned by others, that this *outward pressure* of the air within the lungs is chiefly what so generally cures asthma on the elevated inland plains and mountains of America, by the power it has in stretching the circular, muscular fibres of the smaller bronchial tubes beyond their easy contraction. Report to American Medical Association, June, 1876, on the "Climate of Colorado, and its relation to Pulmonary Diseases."

[2] An exception should be here noted, that this purifying process may be too great a task for the feeble remaining vital-force. Too extensive or far advanced disease in the lungs, the system being saturated with its accumulating effects, may naturally prove too strong an enemy for this or any other purifying process, and in the heated contest which is inaugurated the victim is quickly consumed. Such has been the fate of some who have suddenly risen to great elevations for the sake of restoration to health, when already advanced in the last stage of consumption.

to sustain a quicker but a more perfect life. The loss of flesh in one, and the gain in another (the latter especially for those new-comers for whom *to live* "is gain"), are but the preponderance of waste and repair over each other, which come to all with varying results.

Altitude of Approximate Immunity from Phthisis.

The study of the geography of phthisis gives us an additional and remarkable evidence of the curative influence of high altitudes. For if a mode of life, or a locality of living, should give a large number immunity from this disease, then there is the strongest inference possible that the afflicted who could and would adopt the same manner of life or place of abode might so far enjoy special chances of recovery. Some have thought that an exact line of immunity from consumption could be drawn, depending on altitude and latitude. Among these, Küchenmeister made such close estimates as to give a rule for the altitude of immunity in any latitude. In Switzerland it was 3000 feet,[1] and at the equator 9000, the difference for different latitudes in Germany being 375 feet less for each degree from south to north.[2]

But there are local conditions, variations in the climatic attributes we have thus far considered, which will greatly vitiate any exact rule of this kind. For instance, the Coast Range of the Sierra Nevada Mountains, in California, which condenses much of the moisture from the constant Pacific winds, and renders the high altitudes there uncongenial to most people, would give a very different climate from that of the elevated portions of the next range, and that in turn from the central range running through the continent. It is preferable not to try to defend any positive law, because, if an opponent meets with an instance of the origination of some type of phthisis above the stated elevation, you have attempted too much, and can go no further with him. It is not intended to convey the impression that a given altitude always insures immunity, nor that an approximate immunity may not exist at some low levels, as is claimed for certain far northern lands, and by one M. Maydell for a vagrant and extensive population who inhabit a steppe in Asia, said to be one hundred feet below sea level. We know nothing further of such localities, and are somewhat inclined to consider them like some new gold fields, and many far-off favored localities, where "distance lends enchantment to the view." The argument here intended is that, if twenty to thirty per cent. of all deaths occurring on the coast and borders of rivers are from phthisis, as on the fortieth parallel in the United States, ten to twenty per cent. on higher ground under 1000 feet, five to fifteen per cent. from that height to 2000 feet, two to five per cent. from that to 4000 feet, one to two per cent. from that to 6000, and seldom a case above that point, then the proof is conclusive enough as favoring high altitudes as a resort for consumptives, even though a signal service observer on the top of Pike's Peak should there suffer a lesion of the lung which should eventuate in his death from phthisis (a most improbable supposition). We speak then of an altitude of *approximate* immu-

[1] This is too low by one or two thousand feet, according to the valuable statistics of Dr. Lombard, of Geneva, who, Dr. C. T. Williams states, was one of the first to notice the rarity of phthisis in the high lying habitable districts of Switzerland.

[2] "Die hochgelegenen Plateaus als Sanatorien für Schwindsüchtige," von Dr. Friedrich Küchenmeister, 1868.

nity, which, like the good attributes of high altitudes already discussed, is found higher up as we approach the equator. And herein lies the strongest proof imaginable, outside of the experience of a considerable number of invalids, of the soundness of the combined arguments here presented, in regard to the climatic attributes of high altitudes.

Drs. Weber, C. T. Williams, and Walshe have given, in valuable works already quoted, abundant evidence from mortality records of this gradual decrease of deaths from phthisis originating in high lands. The corroborative evidence of these authors, with others, as Küchenmeister, Brehmer, Lombard, Archibald Smith, Füchs, Nühry, Vacher, Spangler, Jourdanet, Hirsch, and Guilbert, is full and explicit, but would consume more of our time than can now be spared. In general, the altitudes of approximate immunity are at or a little above the elevations given in the first part of this paper for favorable high altitude climates. In America, Dr. E. M. Wight characterizes the inhabitants of the Cumberland table-lands as "a people without consumption," their mode of life probably having much to do with their immunity. Dr. Archibald Smith, who practised medicine a long time in the Peruvian Andes, says that phthisis was unknown above 8000 feet, "except as an exotic," which evidence Dr. C. T. Williams well remarks "is important, because we know that, even up to 13,500 feet, large towns are found in that part of South America, such as La Paz, the capital of Bolivia, and therefore there probably exist some of the causes specially favorable to the development of phthisis." In Mexico, Dr. Jourdanet places the line of immunity at 7000 feet. His personal observation of the rarity of phthisis in the Anahuac, referred to the cities of Puebla and Mexico, where he practised medicine respectively two and eight years. These two cities, comprising a population of 270,000, showed a rarity of the disease, cases occurring only among the poorly fed and scantily clothed class, or "among those natives of the heights whom the interests of business induced to visit lower levels." During his ten years' practice in Mexico, he encountered but twelve cases of phthisis. All occurred among the indigent, a class rendered quite numerous in Mexico by natural indolence, acquired habits, and defect of social organization. In New Mexico, Arizona, and Utah, not a little evidence of an altitude of immunity is shown in communications I have had the pleasure of receïving from army surgeons who have served at elevated stations.[1]

[1] Dr. B. J. D. Irwin reports for Fort Defiance (6500 feet), Northwestern New Mexico:—"Surgeon John F. Hammond, U. S. Army, writing on the diseases of New Mexico, Rio Grande valley, says, 'Phthisis pulmonalis I have never seen in the country, except in two instances, once in an officer of the U. S. army, and once in an American emigrant. It was developed in each before he left the United States, and each very gradually improved. One resided in Lucoro, and the other in El Paso Del Norte.' I can add to the foregoing [Dr. Irwin writes] that during a service of some seven years in New Mexico and Arizona, ranging over a region embraced between the 31st and 36th degrees of north latitude—Fort Union, New Mexico, to Fort Buchanan, Arizona—I never saw or heard of a case of tuberculous disease (consumption) amongst the native inhabitants of those territories. When I went to New Mexico, in 1855, several recruits suffering with well-marked symptoms of pulmonary tuberculosis were sent along with the detachment destined for the troops then serving in that region. I kept track of them after their arrival, and had the satisfaction and pleasure of learning that they all outgrew the tendency to develop phthisis pulmonalis." Surgeon E. P. Vollum, from Camp Douglas, Utah, reports "In an experience of three years and a half in Utah, I have not seen a case of consumption that originated in the territory, and the Mormon physicians declare that no persons born in Utah—excepting Indians—have had the disease, to their knowledge." Among other army surgeons who have written in corroboration of marked immunity at their stations are B. G. McPhail, Camp Apache,

In Colorado, I will place the altitude of *approximate* immunity at 6000 feet. There are good grounds for this decision. I have made quite a thorough canvass of the subject among the physicians of the State, and have found but one case originating above this altitude, and that not very well authenticated—said to have been a case of catarrhal pneumonia of the right apex which afterward improved. Drs. T. G. Horn, of Colorado Springs, and G. S. McMurtrie, of Central, with others who have practised in the mountain districts for a considerable time, have reported that they could furnish no cases of the kind from their experience in Colorado. Between the elevations of 4000 and 6000 feet, however, I have found a few cases. There have been twenty-two in all up to the present date, occurring in the practice of physicians who have most of them resided in Colorado several years. Let us analyze these cases, and learn that it is greatly due to the looseness of the general term phthisis that most of them come under this nomenclature.

Dr. H. O. Dodge, of Boulder, reports four cases from that section; two of the patients have died, and two are not losing ground rapidly; all of these cases commenced with severe colds from exposure; three of the patients probably had pneumonia, and one suppression of menses, which has since continued: time they had lived in Colorado not stated. Dr. Joseph Anderson, of Golden, reports a case of general tuberculosis following miscarriage, rapid decline, and death in four months. Also a doubtful case of abscess following pneumonia in a young man whose father died of phthisis, and which has resulted in apparent recovery. Dr. Jacob Reed, Jr., of Colorado Springs, reports a case in a young man aged 18, three years a resident of Colorado, and with very marked tendency to phthisis by inheritance. Had had slight cough five months when he received a severe injury to one lung, followed by hemorrhage and death in one month. Dr. H. B. Tuttle, of Puebla, has seen two cases "one a sequel to scarlatina, and one following extreme exposure during menstruation, both badly treated, both fatal."

For the city of Denver and immediate vicinity, we have the records of all the deaths occurring since January, 1874, two years and a quarter. These records require information as to the origin of the disease. We find thirteen cases recorded as originating in Colorado. They are of "phthisis," "phthisis scrofulosa," "acute phthisis supervening" as a sequel to other diseases, etc. I have interrogated most of the physicians who reported these cases, and find two acknowledged mistakes, in that the disease existed before the parties came to Colorado; two rapid cases of *Cachexia Africana;* two cases of rapid decline after child-birth; a child one month old, whose mother died of the same disease nine days later; a case of abscess in the base of the right lung following pneumonia; acute phthisis following pneumonia, and hip-joint disease; a case of "whiskey consumption"; a fatal result in a very strong man, after hemorrhage from severe lifting; and a case following scarlatina. Now I cannot see that elevation offers any special antagonism to such cases; and as to accidental lesions of the lung, causing hemorrhage, and also acute double pneumonia, the mechanical influence of rarefied air cannot for the time be considered otherwise than injurious; while phthisis fol-

A. T. ("Arizona as a Health Resort for Consumptives," Virginia Medical Monthly, December, 1874.); W. J. Wilson, Ft. Bayard, N. M.; Oscar A. Woodworth, Mesilla, N. M.; J. V. Lauderdale, formerly stationed at Tucson, Arizona, and C. B. White, Fort Independence, California.

lowing scarlet fever is not to be wondered at, in that the convalescence from special fevers is generally noticed to be tedious in the Rocky Mountain regions.[1]

An additional evidence in favor of an approximate immunity due to elevation may, I think, be gained from the low rate of mortality from pneumonia, as well as from phthisis, as shown by our census statistics, especially as we are coming so generally to consider phthisis as of inflammatory origin; it is that while high altitude increases the unfavorableness of the prognosis of *acute* pneumonia, the ratio of deaths from the disease in the Rocky Mountain states and territories is greatly lessened, showing that there must have been few cases of pneumonia there to have passed into chronic disease.

Experience.

The crowning argument in favor of high altitudes should be the carefully recorded results of the extended sojourn in elevated climates of a good number of consumptives, representing the various types and stages of the disease. In presenting the following table of the records of such of my cases as have been kept under observation more than two or three months during my three years' practice in Denver, it seems to me the shortness of the time is greatly compensated for by only recording the results during the patients' stay in Colorado. It is to be noted that the results, after patients left the high altitude, were generally unfavorable. Those patients who had to be sent away immediately, and those who were not kept under observation two or more months, are excluded from the table, which includes all the other uncomplicated cases of phthisis I have recorded. Three only of the patients had been in Colorado longer than three years, the time of observation specified, while six were in the State the shortest time, namely two months. The period of sickness previous to coming to Colorado, dating back to a persistent cough, pulmonary hemorrhage, hæmoptysis, or evident cause, varied from two months to seven years. Some had resorted to other climates (low altitudes) without benefit. Quite the usual amount of inheritance, in some cases the most decided in my experience, existed in these cases.

Almost all types of phthisis are included, the classification as to the *Nature of Disease* being quite general, and only of account as indicating the usually more favorable prognosis for *inflammatory* than for *chronic tuberculous* cases. As to the *Stage of Disease*, I have endeavored to make close diagnoses, and may have put some cases in the third stage which other physicians would have placed in the second. However, the second stage, in my opinion, does not amount to much in high altitudes, and for practical purposes may as well be considered with the third. If lung tissue has become useless, and "softening" commenced, "excavation" is not far off, with the expansion of the lungs due to elevation. That such a transition is necessarily a part of the high altitude treatment in consumptives so far advanced, will not appear strange to the reflective mind; though its expediency in some acute cases may well be

[1] I have known a case of catarrhal and another of chronic pneumonia, contracted in Denver, in negroes who subsequently recovered, but who would undoubtedly have died from phthisis had they been sick in the East.

doubted. This positive character of the rarefied air prescription leads me to differ as to part of Dr. C. T. Williams's classification. I refer particularly to the "stationary" cases which include a good number of his patients. With the healthful respiratory quickening of high altitudes, the lungs are either not equal to the strain, or they improve under the exercise. I prefer to designate the apparently "stationary" cases of advanced phthisis by what sometimes occurs in them, namely, an extension of excavation, while the resistance of the system to the general effects of the disease is favored by the healthful surrounding influences.

As to whether this table represents the average severity of the phthisical patients who seek relief in Colorado, there is a *pro* and *con* to the question, with a preponderance of evidence in favor of its representing more than the average severity. Invalids whose disease is uncomplicated, and with whom the benefit is immediate and continuous, after their arrival in Colorado, do not, generally, consult physicians there. A proportion of such cases, including many I know to have improved, but of which I have no record of examination, are, of course, not included in the accompanying table. For instance, in the Pullman car in which I left Denver, to come to this Congress, there were four returning health-seekers—three ladies and one gentleman—three of whom went to Colorado in the first stage of phthisis, and the other in the second or third; all of them apparently now enjoy a complete arrest of the disease, and none of them employed a physician in Colorado. On the other hand, a few months after my arrival in Colorado, I wrote an article discouraging the sending there of consumptives with unfavorable complications, after the stage of softening, those affected with heart lesions, etc.,[1] and I am pleased to say that my professional friends in the States have seldom recommended such cases to me. However, the cases are severe enough taken as they are, and I am agreeably surprised with the progress of several having more or less excavation.

Table VI.—*Phthisis in Colorado.*

Analysis of 69 years, 2 months, spent by 66 consumptives in Colorado, with results.

	Number of cases.	Total duration of disease before coming to Colorado.	Average for each case.	Number lost sight of after a time, and probably living in Colorado.	Total duration of disease in years, after coming to Colorado till Aug. 1, 1876, till death, or till departure from the State.	Average for each case.	Much improved or cured.	Slight improvement.	Slight local extension, with general tolerance of disease.	Extension and advance.	Died in Colorado.	Improved, or disease tolerated.	Worse or died.	Died after leaving Colorado.	Fatality evidently hastened by leaving high altitude.	Number now residents of Colorado.

Both lungs affected, 38. Males, 54. Females, 12. Sent away to lower altitude, 7: 3 for heart disease, 1 irritable cavity, 3 far advanced. Became worse by going to lower level, 9

Of these analyses, that in reference to the *stage of the disease* is first and most important. The twenty-five first stage cases were 38 per cent. of the whole, and they averaged over a year and a third under observation in Colorado. Of these, 68 per cent. (17) were much improved or cured, 28 per cent. (7) gained slight improvement, and 4 per cent. (1) died. Of the one unfavorable case, an explanation is needed. A beautiful young lady, age twenty, came to Denver in July, 1875, having chronic laryngeal phthisis with complete aphonia, which had been coming on two and a half years; loss of weight, strength, and appetite, increased of late. Dyspnœa increased, and catamenia absent three months. Grandfather, father, brother, and aunt and uncle, died of consumption, and brothers and sisters living, not strong. Dullness with pleuritic adhesions at base of right lung, and deposit, which I believed to be of true tubercle, at left apex. Slight improvement during the fall. Afterwards she went to live on a ranche, by my advice, with instructions not to mind the loss of voice, but to gain in general strength. Gained seven pounds in two or three months. In February, she followed the meddlesome advice of somebody, and submitted to "throat treatment" from a man who claimed to be a physician, in a neighboring town. The local application of a sixty grain solution of nitrate of silver was a sample of the treatment under which this delicate creature lost thirteen pounds in less than a month. In two months more she died of acute phthisis. I regret exceedingly to have my list marred by such malpractice. Sixty per cent. (15) of these cases are now living in Colorado.

The cases of the second and third stages include a variety, the second embracing several acute, and the third some extremely chronic or prolonged third stage cases. Of the 17 per cent. (11 patients) who were in the second stage, averaging one year under observation, 18 per cent. (2) were much improved; 36 per cent. (4) slightly improved; 18 per cent. (2) had slight local extension, with general tolerance of the disease; in 18 per cent. (2) the disease extended and advanced; and 9 per cent. (1) died in Colorado—or 73 per cent. (8) improved or tolerated the disease, and 27 per cent. (3) became worse or died. Of the 45 per cent. (30 patients) who came to Colorado in the third stage, averaging nine and a half months under observation, 17 per cent. (5) were much improved, 17 per cent. (5) slightly improved, 27 per cent. (8) had slight local extension with general tolerance of disease; in 33 per cent. (10) there was extension and advance, and 7 per cent. (2) died in Colorado—or 60 per cent. (18) improved or disease tolerated, and 40 per cent. (12) worse or died. Of the whole sixty-six patients, 17 per cent. (11) were lost sight of after they had been under observation two or more months; 37 per cent. (24) were much improved; (24) per cent. (16) slightly improved; 15 per cent. (10) experienced slight local extension but tolerated the disease. In 18 per cent. (12), there was extension and advance; and 6 per cent. (4) died in Colorado—or 76 per cent. (50) improved and tolerated the disease; 24 per cent. (16) became worse or died; 48.5 per cent. (32) now reside in Colorado. Thus is shown by evidence, which is abundantly conclusive, the salutary influence of the elevated plains in Colorado upon phthisis—a disease eminently progressive in character. Thus too is shown, what those who live in Colorado have all along believed, namely, that the first or primary stage is pre-eminently the remedial period for high altitudes.

As to *age*, we find 4 per cent. (3 patients) under 20 years old when they came to Colorado, of whom one was the most remarkable example

of inheritance I have ever met; the little fellow weighing two and one-half pounds at birth, and seventeen pounds when four years old, at which time he came to Colorado. His father died of phthisis two months before he was born; his mother had been subject to a chronic cough; and five of her family and six of the father's had died of consumption, with evidence of its existence in the preceding generations. This case comes under the head of chronic first-stage, and the duration is estimated as since birth. The child has been in Colorado four years with gradual improvement. The other two cases under 20 were advanced acute cases. Both became worse, and were advised to leave. Sixty-one per cent. (40 patients) were between the ages of 20 and 30, of whom 42.5 per cent. (17) were much improved; 20 per cent. (8) slightly improved; 17.5 per cent. (7) experienced slight local extension with general tolerance of the disease; in 12.5 per cent. (5) the disease was extended and advanced; and 7.5 per cent. (3) died in Colorado—or 80 per cent. (32) were improved or tolerated the disease; and 20 per cent. (8) became worse or died; 55 per cent. (22) now live in Colorado. Between the ages of 30 and 40, 27 per cent. of the whole (18), resulted as follows: 40 per cent. (7) much improved; 22 per cent. (4) slight improvement; 11 per cent. (2) come under the head of slight local extension with general tolerance of disease; 22 per cent. (4) extension and advance; and 5 per cent. (1) died in Colorado; 72 per cent. (13) improved or tolerated the disease; and 28 per cent. (5) became worse or died. Of the 8 per cent. (5) over 40 years old, 60 per cent. (3) were slightly improved, none being much so; 20 per cent. (1) came under the head of slight local extension, with general tolerance of disease; and 20 per cent. (1) under that of extension and advance; or 80 per cent. (4) improved or tolerated disease; and 20 per cent. (1) worse or died. Thus is shown (as would be more clearly indicated if the first-stage cases were excluded) the less favorable influence of elevation upon young persons with acute phthisis, and upon old persons with chronic phthisis, inasmuch as all but one of those over 40 years of age, were of this latter character.

When we come to analyze the *nature of the cases*, we find 38 per cent. (25) which may be classed as essentially inflammatory; of these 25 patients, 60 per cent. (15) were much improved; 20 per cent. (5) underwent slight improvement; in 4 per cent. (1) there was slight extension and tolerance; 8 per cent. (2) advanced; and 8 per cent. (2) died in Colorado—or 84 per cent. (21) improved or tolerated the disease; and 16 per cent. (4) grew worse or died, three of the four cases being examples of acute cheesy pneumonia. The catarrhal group, 17 per cent. (11 patients), included several in the second and third stages of the disease, and resulted in 28 per cent. (3), being much improved; 18 per cent. (2) slightly improved; 36 per cent. (4) undergoing extension with tolerance; and 18 per cent. (2) advancing—or 88 per cent. (9) being improved or tolerating the disease; and 18 per cent. (2) becoming worse or dying. The third division, chronic tuberculous, naturally embracing many of the third-stage cases, formed 45 per cent. of the whole (30 patients), and resulted in 20 per cent. (6) being much improved; 30 per cent. (9) slightly improved; 17 per cent. (5) undergoing extension with tolerance; 26.6 per cent. (8) advancing; and 6.6 per cent. (2) dying in Colorado—or 77 per cent. (20) being improved or tolerating the disease; and 33 per cent. (10) becoming worse or dying. Excluding the acute and far advanced cases, this analysis shows in a remarkable degree the more favorable influence of the climate

upon inflammatory than upon catarrhal, and upon the latter, than upon chronic tuberculous cases.

It is useful to study the hemorrhagic cases, and to learn what influence elevation has upon this class. Believing that the pulmonary hemorrhages seemingly caused by elevation, which have lately been written about,[1] have been mainly from cavities, I have arranged the 30 cases (45 per cent.) which are known to have been attended by hemorrhage or hæmoptysis, at any time, with reference to the existence or absence of excavation. Seventy per cent. (21 patients) had hemorrhage or hæmoptysis before coming to Colorado; of these, 71 per cent. (15) were probably without cavity and favorably affected, while 20 per cent. (6) were probably with cavity—four coming under the head of "extension and advance." Six patients had hemorrhages both before and after coming to Colorado, five of whom had cavities when they arrived. One patient, subject to repeated hemorrhages before coming, which were much mitigated by a residence in Colorado, subsequently died from metastasis of the disease to the brain, which, by the way, is not a strange occurrence, considering the special influence of the climate upon the respiratory functions. Three had hemorrhage after and not before coming to Colorado. In reference to these three patients, it is well to explain that one with probably no cavity had heart disease and complete hepatization of the right lung—at best a most unfavorable subject for high altitudes. Another had slight hæmoptysis from a cavity while going over the divide; a third, with probable cavity, had hemorrhage, following a chill caused by extraordinary exposure in a storm, and all were evidently little injured by the hemorrhages. On the other hand, four of these 30 hemorrhagic patients had hemorrhage on going to lower levels, three of them being much injured thereby, and two probably dying in consequence. The synopsis of hemorrhagic cases shows a decidedly favorable effect of the elevated climate upon such patients as had had previous hemorrhage without cavity, while a somewhat less favorable effect can be inferred upon hemorrhagic patients with cavity than upon the general average of those with excavation. Therefore, the advantages of high altitudes are pre-eminently for hemorrhagic cases in the first stage, while hemorrhagic cases with excavation should be interdicted from going to great heights.

It would be instructive to compare these results with those in other climates, but we have none at hand so recorded as to furnish very definite conclusions. However, allowing for the absence of similar data in the records of others, the table may be considered as a favorable one, especially for cases in the early stage of phthisis. It is difficult to compare it with Dr. C. T. Williams's records of English and continental resorts, because, in his analyses, those patients who died during the time of observation do not appear to have been included in the estimate. We are only told that "since the climatic treatment 45 of the 243 patients (who spent 386 winters in English stations) have died."[2] Really it would seem to be an important inquiry whether any died during the climatic treatment.

There is strong evidence in favor of high altitudes to be inferred from the experience of Prof. Austin Flint, Sr.,[3] who draws conclusions from

[1] Some Remarks on Diseases peculiar to Mountainous Regions. By W. H. Gardner, M.D., U.S.A., Am. Journal of the Med. Sciences, July, 1876.
[2] Lecture II., Lettsomian Lectures.
[3] "Phthisis," by Austin Flint, M.D., p. 239.

his analysis of 670 cases of consumption, being all he has recorded, but not all those in which he has been consulted. For though he has not kept records of cases for the past eight or ten years, he says, "I should not have omitted to make records of cases of arrested phthisis coming under my observation." With this explanation, he continues, "seventy-five cases must be nearly all in which I have known an arrest of phthisis to take place, either with or without complete recovery, during a practice of thirty-eight years." Now, though there is no analysis of these 670 cases in reference to altitude, several are mentioned, especially among these instances of arrested phthisis, which may be said to have received the special benefit of elevation. Among his patients were several who resorted to the Adirondacks with benefit; seventeen who went to Minnesota, and were, with four exceptions, cured or benefited while there; one who went to the Peruvian Andes and was cured; and one who passed eleven weeks in New Mexico with decided improvement while he remained. Since, on the one hand, there is no evidence produced against high altitudes, and, on the other, so few of those patients who resorted to elevated stations for relief, we are compelled to present the latter fact as the only excuse for Dr. Flint's giving high altitude almost no consideration, and for his arriving at the conclusion "that the benefit derived from the change of climate is due, not so much to a climatic influence *per se*, as to the circumstances incidental to the change." I shall be the last to take issue with this renowned author, or any one else, as to the importance of out-door life and change of occupation; all the most useful means we can combine will not be more than enough to make the consumptive multitude reasonably healthy. Sometimes, by unfavorable cases, the physician is impelled to agree with Pope, that—

> "As man, perhaps, the moment of his breath
> Receives the lurking principle of death;
> The young disease, that must subdue at length,
> Grows with his growth and strengthens with his strength."

Accepting Dr. Flint's collection of cases of arrested phthisis as the largest, or one of the largest, that can be made from the experience of any one man in America, the results of the few cases I have presented must be admitted as an argument in favor of high altitude, in that the ratio of improvement is greater, although covering a shorter period of observation. From my every day experience among the people of Colorado, I am led to believe that as many cases of arrested phthisis (75) could now be found among any average collection of 5000 people at the base of the Rocky Mountains.

One further result of my analysis should not be omitted, so important is its bearing upon the time invalids should remain in high altitudes. The facts noted are that of six patients who have died after leaving the elevation, fatality thereby has evidently been hastened in three; that four of the hemorrhagic patients (a large proportion of those who left the heights) had hemorrhage afterward; and that nearly half (9) of all those who went back to the lowlands, became worse by so doing. Prof. Weber's cases furnish similar evidence: of thirteen cases arrested in high altitudes, two were twice relieved, the disease twice returning on going down to sea level. In six other cases phthisis was rekindled after a descent to sea level; and two patients, who were residents of high altitudes, moved to the lowlands and became consumptive, were apparently

cured on returning to the highlands, and were again taken sick when they returned to sea level.[1]

Jourdanet, among many striking illustrations of a failing or falling off of consumptives after leaving the heights, mentions the case of a young lady who three times went down to a lower level with a return of active phthisis, and three times, in turn, was decidedly relieved by a return to Puebla. Dr. C. T. Williams mentions almost as remarkable an instance of this loss of benefit by the return to low levels. Three of my cases show, in a marked degree, the injurious effect of going from Colorado to Southern California; one patient, in the third stage of the disease, died in two months after leaving the high altitude, and one in the second stage, in the vicinity of San Diego, lost ten pounds, had five hemorrhages, advanced to the third stage, succeeded in getting back to Colorado, and has improved since. A third patient, in the first stage, was one of six young men, four of whom, I believe, were consumptive, who went to Southern California under the restless impulse which often controls such persons. This young man, with two others of his party, were made perceptibly worse by their sojourn in California, and returned quickly to Colorado, considerably disgusted by their experience in the humid air of the Pacific slope. All of these patients were doing well enough in Colorado, and most of them assumed the responsibility of going to lower levels contrary to advice. As Jourdanet expresses it: "I preserve among my notes a great number of examples of the relief of the malady and of the obstinacy of the invalids in returning prematurely to the climate which kills them."[2] And in reference to those who have returned to a lower altitude, he adds: "I often ask myself if actual residence would not have finally vanquished the malady, which a few months' stay had relieved." By inference, I think, an argument might be drawn from the analogous experience of those gymnasts and athletes who abandon their accustomed exercise and so render their lungs liable to disease from lack of use; for we are all the time speaking in favor of healthful respiratory *activity* as opposed to the *rest* which is so desirable in the treatment of most diseases. Such is the experience which leads to the conclusion that a partial recovery necessitates a permanent residence. This statement carries with it the idea, consonant with experience, that complete recovery does not necessitate permanent residence, so that the time invalids should consider it imperative to remain in high altitudes is less for incipient or first-stage cases, in which complete recovery may be expected to occur.

Gathering from these arguments the conclusions which may serve as a guide to the physician in staying the progress of phthisis, many obstacles to successful work may be suggested. Among them, after the hindrances to the patients' following the most useful combination of measures prescribed, comes a difficulty in early arriving at a correct diagnosis of the existence of the disease. It is referable to ignorance and neglect on the part of the invalid, and, I fear, too often to inadequate knowledge on the part of the physician. Often I find the invalid's assertion that his indisposition is slight, that his doctor has examined him and said so, unverified by a correct and careful examination. The previous existence of dyspnœa, night-sweats, loss of strength and weight, are not belied in the real condition of the lungs. We must accept the conclusion which is inevitable, in view of physicians so often differing from each other, as they do, in opinion, that the discovery or invention

[1] Op. cit.

[2] Op. cit., p. 304.

of new means of physical diagnosis, and the thorough teaching of this branch in medical schools, should be earnestly encouraged by the medical profession.

The conclusions of my prolonged, and I fear too tedious, study, I have embodied in the following deductions, in which I respectfully ask your concurrence:—

I. Cool and dry, are better than warm and moist, climates.

II. The most favorable climatic attributes of low altitudes, especially the diathermancy and dryness of the air, are increasingly found with increasing elevation.

III. The favorable or positive influence of high altitude upon the progress of phthisis is best shown in the incipiency of chronic, inflammatory, and hemorrhagic cases; and in others in proportion as these characteristics exist, the more acute the inflammatory process, or the more active the pulmonary hemorrhage, the more gradual and tentative should be the rise in elevation.

IV. Partial recovery necessitates a permanent residence, which is therefore required either in an advanced stage of the disease, or when the recovery has been incomplete.

V. The unfavorable or negative influence of high altitude upon the progress of phthisis, is mainly seen in proportion as the disease approaches or is complicated with the following conditions: First, cardiac disease, if associated with increased labor and abnormal activity of the heart. Second, the stage of softening, in acute cases, associated with extensive deposit, or with an irritable, nervous state, and lack of desirable will power aided by the stimulus and hope of youth.

VI. The generally admitted rule that change of climate and mode of life is favorable to the cure of pulmonary consumption, in proportion to its early adoption, is rendered more stringent in that the results are more positive in case of a resort to high altitudes.

VII. The stimulating effect of high altitude, associated with increased respiratory activity and power, is opposed to the idea of rest, and constitutes a most important agent in arresting chronic phthisis.

VIII. High altitude is a means of arresting phthisis independent of, and in addition to, change of occupation and out-door life, and is worthy to rank with such hygienic measures.

IX. Such is the importance of an early resort to high altitude, that in incipient cases the patient should receive the benefit of the doubt, and the physician give affirmative rather than negative advice, in view of possibility of error in declaring the non-existence of phthisis.

X. High altitude being an important attribute of successful climatic treatment, a resort to a well-chosen elevated climate should constitute part of the physician's advice to every consumptive (who can follow it) for whom the elevation is not specially contra-indicated.

Discussion on Dr. Denison's Paper.

After the reading of the preceding paper, Dr. Thomas S. Duffy, of Rutherfordton, N. C., said:—The paper is a very interesting one. The subject is one of experience and observation. The matter of moisture in the atmosphere is very important. I have known coughs, contracted during dry weather, defy treatment, and yet disappear spontaneously when the weather became damp.

I have taken observations of the difference in temperature between mountain and coast springs, and have found the temperature to be 60° at an altitude of 1500 feet above the sea level, and 59° on the coast. Where I live it is very difficult to find cases of consumption. As this disease is seldom cured, we should consider preventive rather than curative measures. Perhaps the habits of the people of North Carolina are as efficient in creating an immunity from consumption as the climate. North Carolinians are not in the habit of shutting doors to keep out the cold, but increase the heat of their houses, and put on more clothing instead. Going from a warm to a cold atmosphere will not give cold, unless the person exposed has been previously exhausted by exertion. It is customary for people in my State to halt while on a journey and warm themselves, and then proceed in the cold. They do not hesitate, when warm, to plunge into cold streams. Such an act might kill a man coming from the harvest field, because he would be exhausted; but where there is no exhaustion, there is no danger.

I have been in Southern California, and have observed its climate. In the daytime, during the dry season, there is a cloudless sky. After the sun rises, a fog becomes so dense that objects cannot be distinguished at a distance of twenty yards. The atmosphere is heavily laden; the roofs drip as though rain had fallen; vegetation is sustained without rain. It is not observed that the fog induces consumption, but, on the contrary, the people seem comparatively free from it. It is a matter of doubt whether a moist atmosphere is conducive to disease; a moist, cold atmosphere may be, but a moist, temperate atmosphere is not.

Dr. A. S. Baldwin, of Jacksonville, Florida, said:—I am happy to hear the remarks of the reader of the paper upon a subject which I have studied for thirty-eight years in my own State, as far as climate is concerned. It is doubtful whether all the beneficial effects mentioned by Dr. Denison are the result of altitude. I have witnessed the same effects in Florida, where the atmospheric pressure is slightly above 30°, which is assumed to be that of the sea level, so that it appears to be the change of climate rather than the altitude that is so beneficial. I have seen, in a post-mortem examination, lungs studded with obsolete tubercle, the result of disease acquired twenty or thirty years previously, the patient's death being caused by exposure following a debauch; and I have known other cases of consumption, partly cured by the Florida climate, recur when the patients have exposed themselves carelessly. Some medical men administer oxygen as a remedy for phthisis, but I doubt whether this is judicious. By visiting Florida, where the atmospheric pressure is so great, the patient can get oxygen without the effort required for the same purpose in Colorado. This would give rest; and I believe in the value of rest for these diseases, and think that that is one of the reasons why Florida proves so beneficial.

The rain-fall, taking the whole State, is about 51 inches. In my section of the State I have recorded 64 inches in one year, and 31 inches in another. It is impossible to get the truth about the humidity of the atmosphere without taking observations extending over a long period of years.

A sick person requires an even temperature, and we always try to keep them from sudden changes. Experience has taught us this fact. In the excessively dry climate of the western plains there is a change of 60° between the atmosphere of the day and that of the night; surely that is harder on a patient than a change of but 10° or 12°. Therefore, we must have, as one of the components of a healthy atmosphere, enough moisture in the air to prevent such radiation as to produce violent changes. We have that in Florida; we have about 14° diurnal variation throughout the year, and a difference of only 20° in the mean temperature between summer and winter. It seems cooler in Florida than in other places, even when the thermometer indicates the same figures. There is no need to avoid the sun; one can ride or walk in it with impunity, and sunstroke is unknown.

Dr. Henry Gibbons, of San Francisco, said:—When invalids change their location and improve in health, the benefit is attributed to the influence of the new climate and locality, when it is more likely to be due to the mere condition of change. Removal from a better climate to a worse one often does much good, for a time. This fact renders it very difficult to form a correct estimate as to the best resort for consumptives. Our opinions on this subject are constantly changing. Twenty-five years ago it was our custom, in San Francisco, to send consumptives to the Sandwich Islands; but we soon found that to be a mistake. Then we fixed on other localities from which the best reports were returned for a while, until it was discovered that they yielded no permanent good. The climate of Santa Barbara, and of the southern portion of California, was then selected, and every body was confident of their curative power, and hundreds of consumptives came there from all parts of the world. But Southern California is now wearing out. To talk of "the climate" of California is a great mistake. That country has almost as great a variety of climates as all the rest of the civilized world combined. You may journey ten miles across a range of hills, and get from a noonday temperature of 65° into an atmosphere of 105°. The Pacific Ocean, along the coast, has a temperature of 53° or 54°, winter and summer. Put the thermometer in the bay, at the foot of the wharves in San Francisco, in July or August, at high tide, and it will fall to these figures. Of course the superincumbent atmosphere has the same temperature, and this cold air comes in daily during the summer towards noon, as soon as the sun has heated the interior. It often carries with it a dense mist. This is the ocean climate, which prevails only along the coast as far as the first highlands. or where a break in the highlands allows the cold wind to pour through. This cold ocean wind, as it works inland, mingles with the heated air, and forms in many localities a climate highly agreeable and healthful. Farther in the interior, there is a glaring sun, whose rays are never intercepted by a cloud for five or six months of the year. Here the temperature is high by day, and the air very dry, with nights always cool, but never cool enough for discomfort to the invalid. Dr. Denison is mistaken in speaking of the humid climate of Southern California. At San Diego, to which he makes reference, there is but a yearly mean of seven or eight inches of rain. The fact is that consumptives are improved in many climates where a permanent residence may be injurious. I am consulted habitually by letter, and personally, as to the best health resort; but now, after twenty-five years of observation and experience in California, I have ceased to designate any locality. My advice is, to all who have strength enough, "Get a horse or mule, and seek a climate for yourself. Ride, or lie by, as it suits you. Eat good, nutritious food, and drink milk or cream; spend all the time you can out of doors. If you find yourself improving decidedly at any given point, stay there a while, if so inclined, but do not stay one hour after the improvement ceases. Keep moving until you find the right climate and the right place. The chances are that you will get nearly well in searching for it." In confirmed and advanced cases, however, my advice is to go home and die among friends.

Dr. A. B. Stuart, of Winona, Minnesota, said:—Ten years ago I went to Minnesota as an invalid, accompanied by a brother-in-law suffering from pulmonary phthisis, resulting from exposure during the civil war. In two years my brother-in-law recovered, and increased in weight from 125 pounds to 170, and to-day does not have the appearance of a phthisical patient, though when he came he had undoubtedly a cavity in the upper lobe of the left lung. I have often known patients come to Minnesota in the first stages of the disease, and remain until they have considered themselves well. Beneficial effects may be lost, however, by staying too long. If a person is unable to take out-door exercise, Minnesota is no place for him.

Dr. H. A. Johnson, of Chicago, said:—I have known a number of consumptives go to Denver, Colorado, to Florida, to the mountains of North Carolina,

to Georgia, to Tennessee, and to the south of France, and come back enthusiastic about the beneficial effect of the change of climate. It seems that we are all agreed as to the advantage of an open air life, exercise, not pushed so far as to fatigue, sunshine, and good food. Dr. Denison has attempted to establish the fact that in addition to these beneficial influences there is another, viz., altitude. Unfortunately for the solution of the problem he has had to deal with, altitude is connected with all these other influences. How can we separate the influence of altitude from the rest? I believe that in the earlier stages of the disease, patients are benefited by going to the mountains, but, on the contrary, when softening has set in, when cavities exist, I believe that it is hazardous for them to do so. A warm, mild climate is better then. I had about fifty patients last winter in Florida, and they came back better; even those in whose lungs cavities existed were better than they would have been had they staid in Illinois. I therefore think it impossible, in our present state of knowledge, to prove that altitude, *per se*, is beneficial, and will continue to advise patients in the first stages of phthisis to go to the mountains, and in the later stages to go to Florida or Georgia.

Dr. C. J. Hare, of London, said:—I wish, as a stranger, to thank the author of the paper for the valuable facts therein contained on the treatment of phthisis. I have often recommended long sea voyages, and have seen my patients benefited thereby. I have seen patients come back marvellously improved after a voyage to Australia, and an enjoyment of the wonderful climate of Queensland. The region in which phthisis exists, gradually descends from the centre towards the poles. In Iceland and Norway the disease is unknown. It exists in some of the higher valleys of Switzerland, but at the same altitude, where there is plenty of fresh air, phthisis is never found. A winter residence in these places is good, providing the patient can take exercise. To delicate patients I usually recommend a southern, genial climate.

ON THE TREATMENT OF SIMPLE ULCER OF THE STOMACH.

BY

M. LE DOCTEUR H. LEBERT, OF VEVEY;

FORMERLY PROFESSOR OF CLINICAL MEDICINE AT ZURICH AND BRESLAU.

[TRANSLATED BY CHARLES WINSLOW DULLES, M.D., OF PHILADELPHIA.]

THOUGH the difficulty of treating simple chronic ulcer of the stomach often renders our efforts futile, yet there are few diseases in which our art can be of so much service to our patients, both as regards hygiene and by medicinal treatment, properly so called. We must, at the outset, consider the general indications to be met.

I. In the first place we should aid the digestive function of the diseased stomach by selecting for it food easy of assimilation, both from its quality and its liquid form or slight consistency, and by reducing its quantity to that strictly necessary for the maintenance of life, whenever we are obliged as much as possible to spare the labors of the organ. For this purpose we must not omit to call to our aid the absorbent power of the rectal mucous membrane to lessen by so much the work of the stomach; and a suitably regulated diet should always be conjoined with a proper hygiene, both physical and moral.

II. While thus diminishing the work of the affected organ we must guard against unnecessarily fatiguing it with drugs. Since, however, radically curative methods have been, even of late, recommended for this disease by physicians of eminence, I shall not fail to mention them, so as to leave to each practitioner an opportunity for free choice; but I must avow that to this day I incline rather to the expectant method, advising at the same time most careful symptomatic medicinal treatment, in which the true physician may bring to bear all his knowledge, his sagacity, and his desire to be of use to his fellows who suffer, or who are threatened with actual danger.

In the first place, I shall describe the methods proposed by Trousseau, Ziemssen, and Leube.

(1) Trousseau's plan[1] is as follows: The patient takes two or three grammes of the subnitrate of bismuth, an hour before meals, three times a day for ten days, after which time the nitrate of silver is substituted, in pills containing each one centigramme, taken three or four times a day for five days. Then the course of bismuth is resumed for ten days, and followed for four or five days by two daily doses of calomel of one centigramme each. This routine is repeated again and again for three or four months, when it is discontinued, to be resumed after a month's cessation. Evidently this mode of treatment is too systematic, and does not allow for the very varied accidents which may arise and call for modifications during its course.

(2) Ziemssen's[2] method consists in the employment of an artificial

[1] Clinique Médicale, tome iii. p. 96.

[2] Ueber die Behandlung des Magengeschwürs, Volkmann'sche Vortraege, 1871, S. 16.

Carlsbad salt, composed essentially of sulphate of sodium, with a little bicarbonate and chloride of sodium. The patient takes from eight to sixteen grammes each morning, in water heated to 44° R., and should have two or three stools in the course of the day, the quantity of the salt being increased or diminished according to its laxative effect. Gradually small quantities come to suffice.

(3) The method of Leube[1] adds to that of Ziemssen the solution of meat indicated by the author, in which hydrochloric acid in small quantity serves to extract from the meat its nutritious principles. Unfortunately many patients have a repugnance to this solution, which, moreover, does not always bear transportation to distant places. Milk is added to the diet, with Zwieback[2] (or Einback); and by degrees the patient can take a more substantial regimen of thick soups, roasted fowls, etc.

For my part, I prefer to abstain from all radical treatment, placing in the first rank hygiene, and in the second the treatment of symptoms.

I. *Diet and Hygiene.*—Absolute diet, or rather absolute absence of food, should be enforced only exceptionally and very transiently, as after perforation, or immediately after a violent hemorrhage. Then nutritious enemata only should be used. In other cases patients do not bear food well, and we are obliged to give them milk by tablespoonfuls only, every three or four hours, until a larger quantity can be borne. Under all these circumstances, absolute rest in bed is indispensable.

Milk Diet.—It is now half a century since Cruveilhier recommended the use of milk as an exclusive or principal food in the treatment of gastric ulcer, and experience has perfectly justified his plan. For my part, I have seen from it effects often so salutary, sometimes so surprising, that I have, from year to year, become more its partisan. Occasionally a certain repugnance is met with on the part of patients who pretend that they cannot take milk in any form whatever. These cases are rare, and, on the contrary, patients are afterwards grateful to the physician for not having allowed himself to be checked by their prejudices and objections which are often ill founded. The exclusive use of milk is, moreover, rarely necessary for more than from six weeks to two or three months, and by degrees other articles of food can be added to it. Milk is sometimes better borne warm from the cow, sometimes heated, sometimes of the temperature of the room; and iced milk can be taken by some patients who can bear it in no other form. The quantity is increased little by little until fifty, sixty, or one hundred grammes every three hours are successively reached, and total quantities of a litre and a half or two litres are taken during the day—an amount sufficient for good nourishment. Patients who bear only thirty to forty grammes at a time, ought to take it every two hours. At night, feeding should, if possible, be interrupted.

Cow's milk is the most useful kind and that generally employed. Some patients, however, at first bear ass's milk better. Buttermilk and curdled milk, preferred by some, are exceptional forms. Where cow's milk of good quality cannot be had, it may be replaced with goat's milk. Sheep's milk, much the richest in nutritious matters, is sometimes used with success by the owners of large flocks and by their families. At the start

1 Krankheiten des Chylopoetisches Apparats, V. Ziemssen's Pathologie. Bd. vii., S. 113.

2 [Zwieback is made by taking rolls, cutting them in half, and putting them into an oven until they are brown and crisp. These are much used in Germany and Switzerland, crumbled and soaked in some liquid article of food. Einback is simple bread or biscuit.—TRANSLATOR.]

pure milk is sometimes badly borne, especially if there is a marked tendency to acid secretions. In such cases I add one-fourth part of lime water, or as much bicarbonate of sodium as will cover the point of a table-knife. Patients who at the beginning of the milk-treatment are constipated should take one or two cold water enemata daily. When the milk habit is once fairly acquired, then may be added to each cup one or two teaspoonfuls of arrowroot or rice flour; or small quantities of biscuit, of Zwieback, or of white bread may be taken with the milk. Sometimes capricious stomachs—especially in nervous and hysterical women—bear fat substances very well. To these cream may sometimes be allowed. They are the patients who at a later period often bear ham and smoked or salt meat better than fowl, veal, or fillet of beef. It is always well to mistrust the gastric caprices of hysterical women, since their sense of veracity is often warped.

When the stomach is habituated to milk, and partially reinstated in its digestive force, it can be accustomed by degrees to other forms of nourishment; to the farinaceous articles already mentioned, to beef-tea, to Leube's solution of meat; and, better still, to good chicken or beef broth, to which are added farinaceous substances, or small quantities of meat very finely hashed or cut; or the yolk of an egg may be beaten in, or some granulated gluten added—which is very nutritious because of its azotized constituents. Milk-porridges may also be alternated with broths.

Every one knows the great difficulty of getting good milk, especially in large cities, at the seashore, etc. It is, therefore, necessary to have a substitute for milk which can take its place, and be within the reach of all purses. Many years ago I learned to appreciate, in this respect, the excellent milk-powder (*poudre lactée*) of Nestle, of Vevey, which is recognized as much the best substitute for milk in the nutrition of young infants. I have likewise come to employ it much in cases of difficult digestion and embarrassed nutrition, in the treatment of chronic diseases of the adult, especially in that of chronic affections of the stomach, and particularly of ulcer. Since I have lived in Vevey I have thoroughly studied the process of manufacturing Nestle's Farina, and have been able to satisfy myself that the milk used is of the best quality, and that the same is true of the other ingredients, and above all of the methods and manner of manufacture. Fresh milk is first well examined, and then poured into the apparatus, heated by steam, and evaporated *in vacuo* at a temperature which does not exceed 40°–45° C. There is, thus, simple condensation without change of quality. The bread added to Nestle's Farina is made of the best wheat flour, by a plan which preserves its gluten; and the crust alone being reduced to a very fine flour it is so much the richer in azotized constituents. The extremely fine division of the milk in powder, and of the flour of the crust, rich in nitrogen, greatly adds to its digestibility.

A thousand parts of the milk-powder are found by analysis to contain 49.40 parts of water, 931.10 parts of organic matter, and 19.50 parts of ash. The azotized constituents form 21.40 parts in 1000. By microscopic examination I have found a division so minute that most of the molecules do not exceed $\frac{1}{500}$ of a millimetre in diameter, this greatly increasing the facility of mixing with water.

For each meal ten grammes may be mixed or cooked with fifty grammes of water, and gradually the quantity is carried up to twenty grammes in one hundred of water, it being well to warm this mixture to 37° C.

Gradually we may rise to thirty grammes in one hundred, and in place of two or three little meals give one of a hundred grammes every three hours, and even oftener, provided always that the preceding meal appears to have been completely digested. I should be glad if this mode of feeding, which has already gained an established place in the nourishment of earliest infancy, could be thoroughly tested in that of diseases of the adult. And as experimentation in such a matter is better than trusting to any recommendation whatever, I have requested M. Monnerat, one of the proprietors of the article, to place at the disposal of hospital physicians the material necessary for this study; to which M. Monnerat, who is a Syndic at Vevey, has very willingly consented. So that all my colleagues, who would like to experiment with the lacteous powder in pathological nutrition, may address him directly to obtain the quantity required for complete investigation.

In continuing the progress toward a more varied regimen, the stomach at first often bears better well-prepared mucilaginous soups of barley, oatmeal, etc., than broth; to these sago or tapioca may sometimes be added with advantage, and if, besides, they have beaten up in them the yelk of an egg, and contain some finely divided fragments of light meat, these soups can be made as nutritious as they are savory. When, later, we come to allow tender and well-roasted meats, such as chicken, veal, or beef, in small quantity, with a little white bread, it is still needful to enjoin the patient particularly to chew solid food thoroughly, and to eat slowly. We may now also permit a little wine, either pure or mixed with water, at meals. A little later, fish, oysters, and game may be allowed, as well as potatoes, green vegetables, stewed fruit, etc. Too careful a watch can never be kept upon the quality and especially the quantity of food taken. It is well to bear in mind constantly that a single indigestion may undo the good effect of many weeks of prudent and well-ordered feeding.

Tea and coffee, in small quantities, diluted with two-thirds or one-half of milk are allowed comparatively later. The mineral water of Bilin, or that of Vichy, will serve for some time to dilute the wine at the principal meals. From my experience I prefer the natural water of Bilin, in Bohemia, to that of Vichy.

When a patient has become profoundly anæmic in consequence of violent gastric hemorrhage, there is a strong temptation to soon replace the severely prudent regimen by a more analeptic diet—a fault which I have often seen committed. But the more cautiously an increased allowance of food is provided, the more surely is the patient strengthened.

The *hygiene* which accompanies the diet, ought to be conformed to the principles announced. There must be repose of both body and mind, and especially must the patient, after each meal, avoid every rapid or violent movement, as capable of provoking perforation, and must even avoid being too long in a carriage or railroad car. In regard to walking, fatigue must be avoided, and when the patient can resume his occupation he should do so slowly and gradually. It is very essential that a daily evacuation from the bowels should be secured, while any great effort in the expulsion of the contents of the rectum should be avoided. There are also some periods in this disease in which the examination of the patient requires precautions on the part of the physician, in avoiding all strong pressure, and all deep or prolonged palpation.

II. *Symptomatic Treatment.—Pain* is often advantageously combated

by the diet and hygiene indicated. But often, also, we cannot dispense with sedatives; among which opium holds the first rank. The muriate of morphia may be given in doses of one centigramme internally, or better still, by subcutaneous injection. Sometimes suppositories of cacao butter, containing from one to one and a half centigrammes of morphia, may be used, or clysters of eighty to one hundred grammes of water, with ten to twenty drops of laudanum. These as well as the bimeconate of morphia are very soothing, but some patients bear better the extract of opium in doses of from one to three centigrammes several times a day. Other sedatives replace opium very imperfectly, because it acts in much smaller doses, and is equally efficient when combined with alterative medicines which are themselves efficacious against gastric catarrh, such as nitate of silver in doses of one to two centigrammes, and the subnitrate of bismuth in doses of half a gramme, or a gramme, or even more. Brinton recommends the compound kino powder, which contains fifteen parts of kino, four of cinnamon, and one of opium; of this from three to six decigrammes are given at a time. Locally, wet applications to the epigastrium often do much good, acting by cold, if frequently renewed; if left in place, as cataplasms. One or the other method is chosen according to the effect upon the patient. Sometimes large blisters, followed by endermic applications of morphia, give great relief, and in certain rebellious cases moxa, applied to the epigastrium, have done me good service.

Hæmatemesis demands, beside absolute rest, the internal use of small pieces of ice, and its external application to the epigastrium. Among hæmostatics I place in the first rank the aqueous extract of ergot, given every hour in doses of five centigrammes, with the addition of one centigramme of extract of opium. If this fails, the solution of sesquichloride of iron in five-drop doses, given with a mucilaginous liquid, is indicated. In other cases we may succeed better with tannin, in doses of two or three decigrammes, or with acetate of lead, three to five centigrammes, with a little extract of opium added. Alum whey is a good adjuvant draught. If the patient, exhausted by hemorrhage, is in imminent danger of death, generous wines should be employed, with large doses of musk, camphor, etc. When he can again take nourishment, iced milk is much the best food, while nutritive enemata of milk and yelk of eggs, or those of Leube, containing meat hashed fine with sweetbread, may render good service. Enemata of the Nestle's lacteous farina, in doses of twenty grammes to one hundred of water, repeated three times a day, may become very useful. Iced solutions of this powder may also take the place of milk very well, when this cannot be had of good quality.

If the patient gets better, and his appetite returns, we must oppose too prompt a recourse to restorative diet, the consequence being often a renewal of pain and dyspepsia. It is the same with iron, the too early use of which does harm. We should begin with a mild preparation, such as the tincture of the malate of iron, in doses of ten to twenty drops, or the lactate or citrate of iron, and pass but very gradually to average doses and to the stronger preparations. I often order an effervescent ferruginous powder, made up of three grammes of the lactate of iron, nine of tartaric acid, and twelve grammes of bicarbonate of sodium; to be kept in a wide-mouthed bottle, well stoppered, to avoid moisture. The patient takes from a half to one teaspoonful in a small wineglassful of water two or three times a day.

Dyspepsia.—The mistake of attempting to aid digestion by the help

of stimulants and a tonic regimen is often committed. On the contrary, by lessening the quantity and regulating the quality of the food, when dyspepsia is aggravated, much better results will be obtained. And here is applicable all that I have said about diet and hygiene. Excessive acidity of the secretions, or acid fermentation, often form an obstacle to digestion, and in such cases, whatever may be said, the alkalies and especially the bicarbonate of sodium in doses of from one to four grammes are indispensable. The alkaline salts of magnesium, of calcium, and of ammonium, are less well borne in the end, whilst the bicarbonate of sodium, if of good quality, can be taken for quite a long time. An effervescent powder made with bismuth has often done me good service in such cases. It is for these patients, too, that I prefer the natural water of Bilin, as a beverage at meals, to other mineral waters of the same kind, as Vichy, St. Galmier, Vals, etc. The water of Bilin is as alkaline as that of Vichy, and has in it, beside, fixed carbonic acid and sulphates. It can be drunk pure or mixed with a little Bordeaux wine. If the bicarbonates neutralize the acids of the stomach too strongly, the tincture of rhubarb, the extract of orange-peel, the tincture of nux vomica, the bitter tincture,[1] or that of quassia or calumba, modify the secretions advantageously, and act in a more lasting manner, so that it is well to begin their use after that of the alkalies, as soon as the stomach is able to bear them, which is much facilitated by giving them at first in small doses. Among the mineral water cures used methodically, I know none better than that of Carlsbad. When patients are much weakened I make them go through a course of two or three weeks at Franzensbad, after a season of four or five weeks at Carlsbad, where they must take the waters in small quantities, one to three hundred grammes daily, avoiding also the wells that are too warm, and looking upon a temperature of 50° C. as the highest admissible. Some patients even derive more benefit from the use of Carlsbad water when cooled than when at its natural heat. Anti-fermentatives, such as creosote, hyposulphite of sodium, etc., have been highly praised, but have never done me much service in this disease.

Vomiting.—Diet is the best anti-emetic, and here iced milk, aided from time to time by swallowing small pieces of pure ice, may be very useful. Effervescent powders with the subnitrate of bismuth, a mixture of bicarbonate of sodium with lemon-juice, iced soda-water, and saturated alkaline solutions prepared with lemon-juice, with the addition of small doses of laudanum, are the best medicinal remedies in such cases. Pills of opium, each containing one centigramme of the extract, sometimes answer best, three or four being used in the twenty-four hours. Often the iodide of potassium has seemed to me to stop the vomiting better than any other means. I cause four grammes of it to be dissolved in thirty-two grammes of bitter tincture, of which ten to twenty drops are to be taken three times a day.

Constipation ought not to be permitted. Cold enemata and artificial Carlsbad water are good preventives. I often direct two or three pills, each containing five centigrammes of aloes, to be taken before going to bed. The powder or extract of rhubarb suits better for some patients. The essential point is to regulate the stools, without provoking either

[1] [The author doubtless alludes to the tinctura amara of the G. P. which consists of Fructus Aurantii Immaturi, Herbæ Centaurii, Radicis Gentianæ, āā partes ii, Rhizomatis Zedoariæ, pars i, Spiritus diluti, partes xxxv.—TRANSLATOR.]

numerous or liquid evacuations. One stool of moderate consistence daily is enough.

The occurrence of *perforation* demands the most absolute rest and the use of opium in full doses—three to six centigrammes of the extract at first every hour, and afterwards every two hours. The treatment may further be aided by the use of subcutaneous injections of morphia. Absolute diet should be enjoined, and ice may be applied to the epigastrium. This mode of treatment has already proved successful in some cases of this accident, which is one of the most dangerous to which man is subject.

Constriction of the pylorus is usually beyond the resources of art, even the best chosen diet furnishing only unsatisfactory results. In such desperate cases resort may be had to the expedient of washing out the stomach, after the method of Kussmaul.

In conclusion, the patient's *general condition* merits all our attention during the long course of the disease. Primary chlorotic anæmia, as well as that which follows upon a severe gastric hemorrhage, demands the circumspect and prudent use of the ferruginous and bitter preparations already mentioned. The effervescent ferruginous powder is a remedy which I am fond of employing under such circumstances. In summer, the air of the country, of the mountains, or of the sea-shore, may aid the action of an analeptic regimen and of tonics. It is essential also that, even when a cure has been obtained, the patient's diet and hygiene should still be watched over with the greatest care for years.

Discussion on Dr. Lebert's Paper.

After the reading of the preceding paper, Dr. W. Scott, of Cleveland, Ohio, said:—I have listened with great pleasure to this paper, which treats of the method of managing a very troublesome disease. I have always treated gastric ulcer in the manner described by Dr. Lebert. The primary condition to be observed is to keep the organ completely at rest, and to control pain by the use of opium or morphia. I have treated a case of this kind for thirty-one days without having anything nutritious in the stomach during that time.

Dr. H. P. Yeomans, of Canada, said:—I have found, when treating cases in the first stage, when there is much vomiting, that nitrate of silver in pilular form is of service. It may be given in small doses, combined with the compound extract of gentian. I have always found it successful.

Dr. C. J. Hare, of London, said:—Great difficulty is experienced in getting the stomach to retain anything during the course of treatment. I have found that milk, boiled for ten or fifteen minutes, and then skimmed, can be borne by the stomach very often when nothing else can. I think that the language employed in this and many other papers is adapted to create the impression that the disease is more frequently met with than is actually the case. Physicians ought always to be sure that the disease is really present before they begin any particular mode of treatment.

The President, Dr. Alfred Stillé, of Philadelphia, said:—I think the disease does occur frequently. While spending the summer at Lake George, N. Y., at a place where there is scarcely a village population, I have met with no less than four cases among the resident population. I am surprised that the condensed milk used in this country has not been, as far as Prof. Lebert's paper indicates, introduced on the continent of Europe. Condensed milk forms one of the best substitutes for fresh cow's milk that can be found. A gentleman skilled in infantile diseases has told me that he has been able to use it when fresh cow's milk was not tolerated, prepare it as he might. I think it rather

objectionable on account of the quantity of sugar usually employed to preserve it; but it has seemed to answer better than any other form of milk—even than boiled milk. In regard to food, I think that a good deal depends upon its temperature. I have known cases in which no other food than that rendered cold by ice could be retained and digested. A German gentleman, long resident in this country, had been examined by several eminent physicians who were unable to determine exactly what was the nature of his disease, but were inclined to believe it to be cancer of the stomach. After a careful investigation of the case, I concluded that it was one of simple gastric ulcer, and placed the patient under a strict dietetic treatment, when his vomiting ceased, and he gained flesh rapidly, and was able to take long walks and attend to his business as a merchant. He, however, relapsed, and I began to doubt whether I had been right in my diagnosis. The patient then inquired if a voyage would injure him, and asked whether I would object to his consulting several medical gentlemen in Germany. I advised him to consult certain eminent physicians, and wrote out for them a history of his case. He accordingly visited one or more of these physicians, who also regarded the case as one of simple ulcer, but whose treatment was not followed by marked advantage. Another, however, advised food made cold by ice, and no other remedies. The patient immediately began to improve, and returned home, after an absence of four months, having gained fifteen pounds of flesh. This confirmed me in my original opinion as to the nature of the disease. Soon afterwards the gentleman was attacked with hemorrhage of the lungs, and ultimately died of chronic phthisis. After death the lung was found to be universally tuberculous. In the stomach there was no active lesion, but in the greater curvature, and on the posterior wall of the organ, was a cicatrix, consisting of a white spot entirely denuded of the superficial layers of the lining membrane, from which radiated white bands of a fibrous aspect.

Dr. Michael O'Hara, of Philadelphia, said:—In a case of gastric ulcer attended with hemorrhage, I at first used the ordinary treatment with opium and bismuth. The latter drug was not of much service, but I found oxide of silver beneficial. The patient recovered, and some time afterward was again attacked with hemorrhage and recovered a second time under the use of opium and nitrate of silver. Not long since the same patient has passed successfully through an attack of typhoid fever.

Dr. Henry Gibbons, of San Francisco, said:—In the case of a child under my care, fresh and skimmed milk were tried unsuccessfully, and nothing but condensed milk was retained by the stomach. In another case nothing but milk warm from the cow could be tolerated.

Dr. J. W. Smith, of Charles City, Iowa, said:—I recall a case in which nothing could be retained but shavings of ice cut with a plane. The patient recovered, and was able to attend to his business in six weeks.

Dr. Darius Mason, of Prairie du Chien, Wisconsin, said:—A good form of condensed milk is that made simply by the evaporation of its watery portions. The use of the granulated article can be avoided by the employment of this condensed milk.

CASES OF PERNICIOUS PROGRESSIVE ANÆMIA,

WITH

SOME OBSERVATIONS UPON THE ANTE- AND POST-MORTEM CONDITIONS OBSERVED IN THAT AFFECTION.

BY

R. P. HOWARD, M.D., L.R.C.K.,

PROFESSOR OF MEDICINE IN THE M'GILL UNIVERSITY, CANADA.

Before such an audience as the present, and especially in this city, it is not necessary to make many introductory remarks upon the meaning of the terms "idiopathic anæmia" and "progressive pernicious anæmia." Englishmen are aware that, in 1855, Addison, of Guy's Hospital, applied the term "idiopathic anæmia" to a form of "general anæmia occurring without any discernible cause whatever," and "with scarcely a single exception proving fatal." Germans need not be informed that Biermer, of Zurich, in 1872, introduced the name "progressive pernicious anæmia" for the same class of cases, of which he had seen fifteen. And Americans are well aware that, in 1875, Dr. Pepper, of the city to which belongs the honor of entertaining the first International Medical Congress held in America, gave an able *resumé* of what was known on the subject down to the month of October last, together with the history of three cases which he had himself observed.

As the subject is of much importance and interest at the present time, I beg to invite the attention of the Section to four cases of the disease that have crossed my own path, and to some observations upon the *ante-mortem* conditions which have been observed in sixty-two cases, and the *post-mortem* changes found in fifty-one examples of pernicious progressive anæmia.

Case I.—J. H., aged 41, a shipping merchant, known to me for twenty years as of light complexion, average nutrition, and strictly temperate habits; has never had bad health till within two years, during which he has had at times uneasiness after eating, sore mouth, and a gradual loss of strength and color. Residence at the seaside for the last two months has not benefited him; has lost a sister by consumption, but his parents and the rest of his family are healthy.

On September 4, 1874, first consults me; walks in as if tired, and devoid of energy and spirit; complexion sallow, white, different from the hue of jaundice; conjunctivæ and nails colorless; mucous membrane of mouth and tongue very pale, with slight abrasions here and there. Careful examination reveals no disease in thorax or abdomen; liver seems to extend a finger's-breadth below margin of ribs; appetite poor; sense of oppression felt after eating; bowels act every day or two; urine not jaundiced, free from albumen; has not lost blood from stomach, nose, or rectum. Malignant disease was suspected; a careful diet, and pepsin with chlorohydric acid, ordered.

Seen a fortnight later in consultation with Dr. Sutherland, but nothing new was elicited. Patient had been restless at night, and had rather rapidly lost

strength; could no longer walk out, and the ankles had become œdematous in the evenings.

October 16, Dr. Campbell added to the consultation; no additional facts ascertained; agreed that internal carcinoma probably existed; claret and raw beef to be tried. Under date Nov. 1, it is recorded that patient only gets out of bed to have it made; is with difficulty induced to take beef-tea and oysters, which are his only food; sleeplessness persists; slight œdema of scrotum; loud systolic basic murmur; external jugulars pulsate visibly, and fill up from below; a dull, lemon-colored hue of skin; no patches of discoloration in axillary, inguinal, or genital regions; many moles on right side of neck; urine copious, not albuminous; blood pale; no excess of white corpuscles; has not been able to take iron in any form, but has persevered with the pepsin and acid. On November 16, signs of effusion into both pleuræ were detected; these increased, and he died chiefly by apnœa on November 22.

Autopsy.—Drs. Campbell, Sutherland, Ross, and Chipman, present with me. A pint and a half of clear, citron-colored serum in either pleura, and about six fluidounces in the pericardium; both lungs healthy, but extremely bloodless, except at posterior aspect; their bases collapsed; no coagula in venæ cavæ or tricuspid orifice; the latter large, admits three fingers; all the valves healthy. A few fluidounces of serum in the peritoneum; the liver, kidneys, suprarenal capsules, and pancreas, normal; spleen also, and of usual size; gallbladder moderately distended with bile; mucous membrane of stomach exhibits no trace of disease; pylorus and entire intestinal tract in normal state. All the organs, however, very pale and bloodless. Many of mesenteric glands rather enlarged, several of them to the size of a wild strawberry. I regret that as the viscera were not examined microscopically, the existence of fatty degeneration cannot be affirmed. The diagnosis of "cancer" or "latent ulcer of the stomach," was at fault; profound anæmia alone was found to account for death; and the case recalled Addison's description of "idiopathic anæmia."

Case II.—T. W., aged 37, a wholesale dealer in fruit, first consulted me on April 22, 1872, on account of breathlessness and palpitation when walking, and a gradual loss of strength. Sixteen years ago he had a single attack of ague for a few weeks; the only one he ever had. He had resided in Toronto for ten years, and in Montreal for the last eight years; and since then his complexion has gradually become pale, and a former tendency to short attacks of diarrhœa from slight causes has increased. Has not been dyspeptic; has never lost blood beyond a few drops from the nose a couple of times a year when suffering from a cold. For the last twelve months his complexion has been very pale.

He is an only son, and has had but one sister, a healthy woman. His father died suddenly of heart disease, at twenty-seven years of age, and his mother of some bowel affection; she had been subject to rheumatism. Patient is a large-framed, well-nourished man, but the subject of extreme pallor of the general surface, lips, and lining of the mouth, without œdema of ankles or eyelids. The pulse is small, soft, and regular; a soft systolic murmur, audible at mid-sternum, is propagated up the pulmonary artery and aorta; a continuous hum is heard in the jugular vein, and along the right border of the upper sternal region. The limits of the liver are normal; those of the spleen perhaps slightly increased. The urine is free from albumen; the appetite indifferent. A generous diet, claret, and a combination of iron and quinine were prescribed; and in June he was sent to the seaside, with instructions to persevere with the above measures. He was very much benefited, and did not revisit me till the February following (1873), when he presented the original symptoms of profound anæmia more intensely than before. A drop of blood from the finger-point was watery-looking and of a very pale red color, but contained no excess of white corpuscles.

A careful examination in conjunction with Dr. Campbell failed to discover any disease in lungs, heart, liver, spleen, or kidneys; nor had the patient

been suffering of late from diarrhœa or dyspepsia, although his appetite had been failing for some time. We agreed that the case was probably one of "idiopathic anæmia," like the previous one which we had seen together. All the various remedies, including iron, quinine, pepsin, etc., except phosphorus, that could be rationally prescribed, failed to meet the increasing pallor and failing strength. Food was given by mouth and rectum. The pulse grew smaller and weaker; faintness followed sitting up in bed; the appetite completely failed—indeed, food was loathed; the bowels became very torpid; epistaxis, sometimes severe, became a frequent symptom; a moderate elevation of temperature was noticed many times; his spirits sank, and towards the last a feeble delirium and childishness were observed now and then; œdema appeared in the legs, and death by exhaustion took place on April 22, exactly a year from his first interview with me. No autopsy could be obtained, so that the diagnosis of "idiopathic anæmia" wants that confirmation. No other view of the case, however, I submit, appears more rational, neither "Hodgkin's disease" nor latent carcinoma. This defect does not exist in my *third* case.

Case III.—Mr. T., aged 53, lost his wife very suddenly in her first confinement, about five years ago. Has been known to me for over twenty years as a temperate and healthy but not robust-looking man, which his occupation as a book-keeper may perhaps account for. He consulted me first in August, 1872, for a slight diarrhœa. He next came under observation in April, 1874, suffering from dyspepsia, which was benefited by pepsine and muriatic acid. On August 31, he still complained of epigastric uneasiness after eating, and looked more delicate, paler, and more spare than usual. No local disease in the abdomen could be discovered however, and nux vomica and cod-liver oil were advised in addition to the pepsine mixture. He did not return till Jan. 30, 1875, when he looked much paler and very sallow, and complained chiefly of weakness, so that he had of late driven to his office. A few days before he had passed blood at stool, but the hemorrhage did not recur. The anæmic looking surface was of natural temperature; the pulse 72; no enlargement of spleen, liver, or external lymphatic glands could be detected. The urine, free from albumen, deposited uric-acid crystals freely, and had a sp. gr. of 1030; no discolored patches on any part of body.

In the latter part of February diarrhœa occurred for a few days; patient's weakness and pallor were rapidly increasing; a soft systolic basic murmur was noted, and a drop of blood from the finger was pale and watery. The microscope showed no excess of white corpuscles; nine or ten only could be counted in the field, and they looked smaller than usual. The surface was very pallid and of a somewhat light straw color. In addition to pepsine at his meals, a pill containing reduced iron and nux vomica was prescribed, with beef-tea, claret, etc.

March 4. Urine still the color of pale sherry, and sp. gr. 1020. Deposits uric acid; is free from albumen; feet and legs œdematous. To have in addition to the ferrum redactum, $\frac{1}{50}$ gr. phosphorus (Warner's pills) after every meal.

He had been seen by Dr. Campbell in consultation with me on March 2, and no organic disease could be detected to account for the serious anæmia and prostration. Of course the case reminded us of our two previous examples of "Idiopathic anæmia," and as such I told the friends I regarded it. After this the downward course was rapid. Soon vomiting and a tendency to diarrhœa appeared. The appetite failed; the pulse grew gradually more frequent, 78, 84, 90, 102, and became weak and jerking, though regular; a constant "beating" in the head was complained of; faintness was experienced on sitting up in bed; and a mild delirium at night was followed by childishness and want of purpose in the day. The eyelids became somewhat puffy; the urine retained its high density and color, although the temperature of the body did not exceed the normal till a few days before death; fewer white corpuscles were found in the blood on March 18, three in one field and one in another;

the red corpuscles were of course deficient, but no attempt was made to estimate their number. The stain made by a drop of blood upon a white handkerchief was very pale. The voice grew feeble; the body wasted somewhat; the bloodless appearance of skin, mucous membrane, and nails, increased; and, during the last three days of life, a progressive stupor, dilatation of the pupils, slackening of the pulse-rate, retention of urine, and labored respiration, indicated a suspension of the cerebral functions. At this time the temperature of the body became somewhat raised. He died on March 28, 1875.

Autopsy,[1] twenty-seven hours after death; moderate cadaveric rigidity; some subcutaneous fat; no blood escaped while opening cavities.

Thorax.—About two fluidounces of clear citron-colored serum in left pleural cavity. Some bridles of adhesion over apex of left lung, in which are found two or three dry, black and white caseo-calcareous masses, almost the size of a small bean, and surrounded by a capsule of pigmented and indurated tissue. The right pleural cavity obliterated by very firm adhesions; in the extreme apex of right lung a patch of black indurated tissue about an inch in diameter, and a separate small nodule of mortar-like material. The rest of both lungs healthy, but œdematous, and very anæmic looking. Bronchial glands not enlarged. Pericardium contains about four fluidounces of serum; a good deal of fat on right side of heart; scarcely any blood in cavities of heart; very small colorless coagula in both ventricles; valves normal.

Abdomen.—Liver normal; half a fluidounce of green bile in gall-bladder; spleen very small, firm, and its capsule shrivelled; cut surface pale and smooth; mesenteric and lumbar glands unusually small; stomach and intestines perfectly healthy, but their coats very pale; supra-renal capsules and kidneys normal; all these organs contain very little blood.

The spleen, a portion of the heart, and blood from the splenic vein and from the inferior vena cava were taken away for microscopic examination by Dr. Osler, to whom I am indebted for the following report, as well as for other valuable assistance in the preparation of this paper:—

"*Blood* from the inferior cava and the splenic vein: The colorless corpuscles did not appear in any excess, averaging in a number of observations from six to eight in the field of No. 7, ocular 3. They presented slight variations in size, and the protoplasm was rather more granular than normal. Clusters of from six to ten adhering together were not uncommon. Nuclei variable; some had only one, others two or three. In the blood from the splenic vein the colorless corpuscles presented the same characters; a few retained their amœboid movements when placed upon the warm stage. Max Schultze's granular masses were abundant, and some of large size; the individual elements composing these masses were very distinct. The red corpuscles looked natural, a few only were crenated; a somewhat unusual variation in size was noticed among them. Many measured scarcely the $\frac{1}{5000}$ of an inch in diameter as seen with the No. 9 (immersion).

"*Spleen.* Weight one ounce and five drachms. Portions teased in saline solution and examined with the No. 9 (immersion) showed the ordinary structures met with in the organ (pulp cells, blood corpuscles, and connective tissue). The elements of the latter, as might be expected from the diminished bulk of the organ, were in excess, and consisted of the fibrous tissue of the trabeculæ and numerous nucleated fibre cells. Examination of their sections yielded the same results; the elements of the organ appeared normal, there being simply a disproportion between the connective tissue and the pulp.

"*Heart.* A small portion of muscle from the left ventricle showed marked signs of fatty degeneration."

I regret that the bones were not examined in either of these cases, but Dr. Pepper's paper had not been published when the last of them termi-

[1] My friend Dr. Osler kindly assisted me at the autopsy; Drs. Campbell and Chipman were also present.

nated. In the second autopsy a condition was found that, as far as I am aware, has not been hitherto observed in this disease, viz., marked atrophy of the spleen and great reduction in size of the mesenteric and prevertebral lymphatic glands. At first, I thought that this condition might account for the oligæmia in that case, but the subject of hæmatopoiesis in the adult is so unsettled that I do not venture to express an opinion as to the relationship existing between the anæmia and the state of the organs in question, although they are generally supposed to be concerned in the elaboration of the blood. A symptom observed in this last case that interested me much during life was the high color and density of the urine. It did not resemble the urine of ordinary anæmia, but rather that of rheumatic fever; and I am disposed to refer it to an excessive destruction of the red globules, as neither fever nor rapid wasting were present.

A fourth example of this disease came recently under my notice, in consultation with Dr. Greene, of Granby, to whom I am indebted for a report of the case.

Case IV.—Mrs. W., ætat. 46, a highly respectable married woman, the mother of four children, of whom two survive, and are robust and plethoric. In early married life she had had a few slight attacks of epistaxis, but had enjoyed tolerably good health till within about two years of the menopause, during which period menorrhagia existed. Then her health began to fail, and she became somewhat anæmic. No cause could be found in the condition of the organs for the hemorrhagic tendency. When first visited by Dr. Greene, nearly two years after (in March, 1875), she presented all the symptoms of intense anæmia, including the blood-murmurs in the great vessels. The only evidence of local disease discoverable was some fulness and tenderness of the liver, irritability of the stomach, and a yellow tinge of the conjunctiva. Although the digestive disturbance disappeared and she was able to enjoy carriage exercise during the summer, and had a very good appetite, the anæmia increased, and she had two or three slight attacks of epistaxis. In October the gastric symptoms returned with increased severity, and an aphthous condition of the mouth and fauces, which she had had more than once before, recurred, and was attended with slight diarrhœa, with a daily augmentation of the temperature, which could not be controlled by quinine or salicine. When seen by me last winter, in consultation with Dr. G., she was unable to leave her bed, and exhibited all the symptoms of advanced anæmia. A careful examination of all the organs, including the uterus, rectum, external glands, spleen, liver, etc., failed to detect local disease, and I expressed the opinion that it was a case of "progressive pernicious anæmia." A drop of blood taken from the finger-point was thin and pale in color; but was so spoiled by drying when I got back to Montreal that Dr. Osler could not satisfactorily make out its characters. The patient died on January 17, from exhaustion, preserving her mental faculties to the last. She had had two or three very moderate losses of blood from the nose since she had been seen by me.

Although satisfied in my own mind that the case just related was one of pernicious anæmia, yet as the diagnosis lacks the verification of an examination of the blood during life, and of the body after death, I would not have related it but that the family history appears to me important as proving that a predisposition to anæmia may exhibit itself in families and that it may perhaps be inherited.

This last patient's youngest sister has been anæmic since childhood; a married cousin has been anæmic since having an attack of typhoid fever about two years ago; and a grand-uncle died at sixty-two, with symptoms like those manifested by the niece, and was anæmic. Judging

from the papers which have been of late written upon this subject, it is not generally known that Dr. Wilks,[1] of Guy's Hospital, in 1857, published a series of cases of the disease we are considering under the caption, "Cases of Idiopathic Fatty Degeneration." "This designation," he remarks, "is given to a class of cases in which an *excessive anæmia* and *debility* are the peculiar phenomena observed during life, and a fatty degeneration of all parts of the body, but especially of the heart, the most remarkable appearance found after death." And further on he says, "The following seven cases will afford examples of this remarkably fatal anæmia and fatty degeneration." Two years[2] later, when describing another case of "Idiopathic Anæmia," he applies the latter title to his former series of cases. What a notable anticipation of Gusserow's observations in 1871, and of Ponfick's in 1873. It is due also to Prof. Lebert to say that he was one of the first to call attention to our subject. In 1853 and 1854 he had met with six cases of what he called "Puerperal Chlorosis," only one of which, however, had terminated fatally; and in 1858, under the title "Essential Anæmia," he published the details of that fatal case and of another subsequently observed, together with the appearances found after death. His third fatal case, with autopsy, occurred in 1859.[3]

These series of cases of Dr. Wilks and Prof. Lebert are not mentioned in Dr. Pepper's able paper on the subject, nor are the single cases of fatal anæmia published by Dr. Combe[4] about 1823, by Sir Dominick Corrigan in 1844, by Dr. Dickinson in 1863, and by Dr. King in 1871; nor Dr. Barclay's two examples published in 1851.

I have met with ten alleged examples of pernicious anæmia recorded since the appearance of Dr. Pepper's article: the first by Dr. F. Fedé[5] in October, 1875, however, appears to me to have been an example of so called "Myelogenous Pseudo-leukæmia," as the spleen was found after death of threefold the normal size, and its firm pulp "consisted of somewhat larger cells than in the natural condition, and they appeared very similar to the elements of the bone-marrow." The bones of the skeleton were thickened, the compact substance much reduced and replaced by a wide meshed spongiosa, in which the microscope found similar structures to the normal red marrow of bones; there were, however, numerous multinuclear (growing) cells and blood-corpuscle-containing elements. The liver, also, was a little enlarged; the blood contained no excess of white corpuscles.

In December, 1875, Dr. Pye-Smith[6] published two cases of "Pernicious Idiopathic Anæmia," with autopsies. Both occurred in men; no cause could be assigned for the disease in one; in the other, possibly, one or two attacks of intermittent fever experienced seven years previously may have stood in that relationship. The only morbid appearances discovered at the examination of the cadavera were fatty degeneration of the heart in both, of the liver in one, and thickening of the mucous membrane of the stomach in one. The bones were not examined.

This year Dr. Scheby-Buch[7] has recorded two cases of "Essential Anæ-

mia." It is open to question whether either deserves the title of "Essential," as the man, aged 48, had had "ulcers on his legs which discharged from Easter to Christmas," and the woman, aged 60, had been "sickly for several years." The spleen was found enlarged in both. In the female there existed, in addition, dilated bronchi, fatty degeneration of the viscera, and "numerous cells resembling white corpuscles, in groups," in the marrow of one radius. The marrow was pale-red, and contained but "few fat cells," and only a few red globules. (Perhaps these cases ought to be regarded as examples of pseudo-leukæmia. I have retained them however.)

In the number of the Centralblatt for June 24, 1876, there is a notice of three cases of this disease recorded by Krieg,[1] and an autopsy. Only a very meagre report is given, and I have not been able to procure the original paper. Two of the three patients were men, aged respectively 52 and 45 years, and in good circumstances. No other details of these cases are given. The third case was that of a married peasant woman, aged 48. How many children she may have had is not stated. It is simply observed that she had been ordinarily stout till within a year. During that time petechiæ appeared upon the lower limbs, bleeding took place from the gums, and pleurisy set in. The autopsy revealed visceral hemorrhages, fatty degeneration of the heart's fibre, and a fibro-sarcoma at the base of the brain. Nothing is said about the condition of the bones.

An instance of this disease is related by Dr. E. H. Bradford, in one of the July numbers of the Boston Medical Journal for this year. The case is interesting, as affecting a girl only eleven years old, the earliest age at which the disease has been observed. No cause could be discovered. The blood globules were reckoned during life, and both red and white found to be numerically deficient. The red were paler than normal, and had lost their biconcave contour. "There was not much variation in size between the individual globules. All were smaller than usual. There was not much detritus. The white globules seemed abnormally granular, and were irregular in shape."

Amongst the peculiar symptoms mentioned, are severe pains in the ear and abdomen, and severe attacks of pain in different parts of the body; a daily expectoration of blood to the extent of about three ounces, and upon one occasion equal to a pint. The temperature during the three weeks before death, ranged from $101\frac{1}{5}$° F. to $99\frac{4}{5}$° F. Death was preceded for a day or two by loss of consciousness, a firmly contracted and flexed condition of the right arm, and a motionless state of the right leg. No disease of the spleen, lymphatic glands, lungs, or other organ could be detected during life. No autopsy was made.

The latest reported case that has come under my notice, was brought before the Société des Hôpitaux, on July 14, 1876,[2] by M. Lepine. The anæmia began with the third pregnancy of a delicate woman, who, however, had never been the subject of any serious disease, although she had many times suffered from gastric troubles. A careful post-mortem examination discovered only a circumscribed fatty degeneration of the heart, and an insignificant unilateral broncho-pneumonia. No disease of the spleen, glands, or bone-marrow, existed.

I have not tabulated Ponfick's, Grofner's, Quincke's, or Grenville's

[1] In Würtemb. Corr. Bl., 1875, No. 39.
[2] Vide Bulletin Générale de Therapeutique, 30 Juillet, 1876, pp. 85–87.

cases, not having been able to procure their details. Zenker's case of anæmia due to uterine hemorrhage, and Chadwick's case arising apparently from post-partum hemorrhage, I have also not tabulated, as they are at least not typical cases. For a like reason, I have excluded a case of extreme anæmia which occurred under my own care in a puerperal patient without undue hemorrhage or other evident cause to account for the profound anæmia; from which, however, she recovered after a long struggle. Perhaps all cases of recovery from apparently pernicious anæmia, should, in the present state of our knowledge, be excluded, while they should be very carefully studied in the hope that they may shed light on this obscure department of pathology.

An analysis of these cases of pernicious anæmia suggests the propriety of dividing them into distinct classes or groups, and even it may be of refusing to some of these the title of "idiopathic":—

Group I.—Thus all the cases which occurred during *pregnancy* ought to stand by themselves, for while no sufficient reason can be assigned why in such females the usual moderate impoverishment of the blood, which obtains during gestation, should have attained such a development as to have proved fatal, yet the existence of so well characterized a constitutional state as that of gestation, as a condition common to so many of the examples of so-called pernicious anæmia, cannot well be regarded as accidental. To this class belong by far the largest proportion of reported cases. All of Gusserow's five cases were in pregnant females; several of Biermer's were; one of Lebert's fatal cases, and one of Wilks's were; Corazza's only case was that of a woman who had had four children in five years, and died soon after delivery, and the latest reported case, Lepine's, began with the third pregnancy of a middle-aged woman who had only suffered from attacks of gastric disturbance.

Group II.—Some examples of the disease followed so closely upon *parturition*, quite independently of undue losses of blood, that they should perhaps be called puerperal cases. One of Marshall Hall's cases, one of Barclay's, and some of Biermer's, appear to have been in some way connected with the puerperal condition. Indeed Lebert met with several examples of severe anæmia under conditions which induced him to draw special attention to an "acute puerperal chlorosis," and many authors have written upon the chlorosis of pregnancy (notably Beau, Andral and Gavarret, Regnault, Cazeanx, and Sée).

As by far the largest proportion of the recorded examples of fatal pernicious anæmia have occurred during pregnancy and soon after delivery, it would be important to be able to arrive at an explanation of the relationship between child-bearing and pernicious anæmia. This is perhaps not possible. Even if it be urged that frequent child-bearing and more or less prolonged lactation may be regarded as spoliative processes of no mean power, and that amongst the poor, in whom these influences are especially prevalent, there is very frequently an insufficient supply of generous food and pure air to meet the spoliation, and hence the impoverished blood, it is difficult to comprehend why it is that pernicious anæmia is after all so seldom met with, while the influences just mentioned are so prevailing. Moreover, fatal anæmia occurred in one of Gusserow's cases during the first pregnancy, a circumstance which, in the light of the preceding observations, renders it probable that the pregnant state *per se* predisposes to progressive blood deterioration, an idea somewhat borne out by the rapid course of the disease in all Gusserow's

cases, one of them lasting only five weeks, from first to last; two occupying but four to five months; a fourth even less time; and the last ending in the eighth month of gestation.

Group III.—Closely allied to the pernicious anæmia of pregnancy appears, on first thought, that common affection still styled *chlorosis*. The latter, like the former, is most frequent in females; it is very generally accompanied by disturbance of the uterine functions, and its causation is unknown. On second thought, however, there is the striking difference that chlorosis very seldom proves fatal, while the anæmia of pregnancy appears to do so frequently; the former is amenable to treatment, the latter rarely if ever is cured.

The only examples of fatal anæmia in *young* females independent of pregnancy that I have tabulated are three cases recorded by Marshall Hall; one by Wells in a married woman 31 years old; one by Immermann, in a patient also married and of the same age; one by King in a woman, aged 27, who had had since puberty more or less menorrhagia and leucorrhœa; one by Pepper, in a woman aged 36, who had been exposed to malaria and had had bronchitis for five months before the anæmia appeared, and Bradford's case of a girl only 11 years old. Of these eight cases, only two, one of Marshall Hall's, in a girl of 18, and Bradford's case, can be fairly cited as typical examples of chlorosis proving fatal, and so far resembling pernicious anæmia. Inasmuch, then, as the ordinary chlorosis of young women is notoriously very seldom fatal, while that less frequent form incident to pregnancy frequently is, we may not conclude without further light that both forms of anæmia acknowledge the same causation, although we may grant that both may be called "idiopathic" or "essential," until some satisfactory explanation of their origin is forthcoming.

Group IV.—Another group comprises those cases which have been preceded by *chronic diarrhœa*. Biermer states that pernicious anæmia frequently follows that affection; but, with the imperfect history given in very many of the published cases, his observation remains unproven. It is true that diarrhœa is frequently mentioned among the symptoms of the affection, but many authors fail to say whether the diarrhœa preceded the other evidences of the disease, or merely accompanied them. Indeed, beside the cases given by Biermer, the only others in which chronic diarrhœa is recorded amongst the antecedent conditions of the anæmia are: Corrigan's case, in which diarrhœa had existed "off and on for years;" one of mine, in which a tendency to that affection had been observed over eight years; and one of Pepper's, in which "chronic follicular catarrh of the intestines had existed for many years;" this patient had also "chronic suppuration of the gall-bladder," and a former history of psoriasis of twelve to fifteen years' duration. These facts, then, scarcely bear out Biermer's statement.

Diarrhœa formed a leading symptom in the following cases: two of Lebert's; three of Wilks's, in one of which there were cicatrices and ulcers in the colon; one of Barclay's; one of Pye-Smith's, and Lepine's case—in all eight. But it appears from the notes of all these cases that an impoverished condition of the blood coexisted; and also some one or more of the other conditions known to have preceded or accompanied pernicious anæmia in other cases, such as pregnancy, parturition, hemorrhage, etc.

Group V.—Six more of the tabulated cases may be grouped together, inasmuch as the antecedent conditions were such as to involve *blood-*

waste; they might have been included with the last group, which also implies blood-waste, had not previous writers attached so much importance to chronic diarrhœa *per se* in relation to pernicious anæmia. Such are Wilks's case of an errand boy, aged sixteen, who had not been well for three years, and had often suffered from epistaxis, and whose colon contained cicatrices and ulcers; King's case, which had been preceded during thirteen years by menorrhagia and leucorrhœa; my fourth case, in which for two years before the cessation of menstruation, there had been menorrhagia; one of Pepper's cases, preceded by chronic bronchitis for five months; and Buch's two cases—one sickly for years, and the subject of chronic bronchitis and an abnormal condition of the marrow of the radius; the other, a case of pernicious anæmia, closely following upon ulcers of the legs, which had discharged freely from Easter to Christmas.

Cases of fatal anæmia occurring in persons who have long suffered from repeated attacks of loss of blood, or from protracted leucorrhœa, or from chronic bronchitis, or from chronic ulcers, while they may be in one sense included in the title "progressive pernicious anæmia," cannot strictly be regarded as examples of "idiopathic anæmia" as delineated by Addison in his masterly description of the disease. He confined the term to "cases in which there had been no previous loss of blood, no exhausting diarrhœa, no chlorosis, no purpura, no renal, splenic, miasmatic, glandular, strumous, or malignant disease."[1] This is a point which has been so much overlooked of late that the terms "idiopathic anæmia" and "pernicious progressive anæmia" are not now synonymous.

GROUP VI.—There is a group of six cases (one by each of the following writers: Broadbent, Pye-Smith, and Lebert, two by the author, and one quoted by Buch) occurring in patients from forty-one to fifty-seven years of age, in which no antecedent condition is mentioned sufficient to cause the anæmia except *dyspepsia.* In only three of these did the indigestion last a considerable time, and in one of them (a case of my own) it was not severe. In the other three cases the dyspepsia occurred rather among the early symptoms than among the antecedent conditions. It must be admitted that even severe and protracted dyspepsia very rarely induces a fatal anæmia; and I incline to regard the relationship in these cases as that of coincidence only.

GROUP VII.—*Extreme poverty* or *poor diet* were the conditions under which pernicious anæmia was observed in four men (Lebert, Wilks, Dickinson, and Cazenave, each a case), and if these were the real causes of the blood disease, such cases require little discussion; the anæmia is merely a consequence of inanition. But why this fatal form of anæmia is comparatively so rare, while poverty and poor diet are so frequent, we cannot say.

GROUP VIII.—A remarkable case is related by Pepper, in which a man, after having had *jaundice* "about a month," then exhibited well-marked anæmia which proved fatal. In Corazza's case severe icterus was also an antecedent condition, but the patient was also pregnant, and had had four children in five years.

GROUP IX.—Finally, there remain nine cases in which no antecedent condition is mentioned that can fairly be regarded as causative unless it be a case of Pye-Smith's, in which there may have been two slight attacks of intermittent fever, years before, "although on this point [the patient's] account was somewhat uncertain," and two of Wilks's, one, in which

[1] Addison's Works, Syd. Soc. Ed., p. 212.

"domestic trouble and recent marriage" coincided with the appearing of the anæmia; the other, that of a woman aged fifty who had been "thirteen years in a lunatic ward." Failing health and progressive anæmia are a summary of the conditions mentioned in the whole nine cases (Wilks three, Barclay, Combe, Pye-Smith, Lebert, Immermann, and Howard, each one[1]).

It results from this analysis that the conditions—as far as they are known—under which these cases of pernicious anæmia originated, may be thus grouped:—(1) pregnancy especially where oft repeated; (2) parturition (and these two conditions appear to be especially frequent); (3) chlorosis, which is rare; (4) chronic diarrhœa or intestinal catarrh, which is by no means as often antecedent as some authors state; (5) blood-waste, direct and indirect, from protracted menorrhagia and leucorrhœa, from chronic ulcers, from chronic bronchitis, and from repeated epistaxis combined with ulceration of the bowels, conditions present in six cases; (6) dyspepsia, observed in three cases; (7) extreme poverty or poor diet, mentioned in four cases only; (8) jaundice, the only known antecedent in one case, and associated with frequent child-bearing in another; and last (9) no antecedent condition mentioned other than "failing health," which must exist when anæmia is developing.

Reflecting upon the frequency with which these several conditions obtain, they cannot fairly be held to be frequently productive of, or antecedent to, a progressive pernicious anæmia, and some of them seem to be quite incapable of producing so grave a disease. The conclusion is almost inevitable that either an inherited or an acquired predisposition to defective development or regeneration of the blood must exist in these cases of pernicious anæmia, otherwise such conditions could not be followed by such profound and unmanageable alterations of the blood.

Passing from the *ante-mortem* to the *post-mortem* conditions, it cannot be said that Morbid Anatomy has thus far explained the occurrence or the nature of the disease.

1. The *fatty degeneration* of the heart and other viscera first specially insisted upon by Wilks in these cases of fatal anæmia, is a consequence, not a cause, of the blood impoverishment, and is observed also after severe hemorrhages, and in protracted fevers, in starvation, and other analogous conditions.

2. The *small size* "hypoplasia" of the *heart* and of *the large arteries*, pointed out by Virchow as existing in some severe cases of "chlorosis," and which may be regarded perhaps as congenital, even if it were proved to be constant in chlorosis, could not be anticipated in the other forms of anæmia included under the term pernicious. It is true that we have not many observations on this point, because the subject has not been generally investigated. However, Pye-Smith found "the aorta of proper size and its coats healthy" in his second case; its condition is not given in his first; in both the heart was over the average weight. Buch, after comparative measurements, did not find the aorta smaller in his two cases than in other anæmic and cachectic bodies, if not so wide as in healthy persons.

3. In fifty-one autopsies of progressive anæmia that I have collected, either the *spleen* is described as normal, or the "viscera" (and therefore the spleen) are said to have been normal, thirty-six (36) times; as more

[1] Not having been able to get Krieg's original paper, I cannot say anything of his cases.

or less enlarged, usually but slightly, thirteen (13) times; once (1) as small and shrivelled; and once (1) its condition is not stated (Krieg's case):—

Spleen normal	36
" enlarged	13
" small and shrivelled	1
Condition not stated	1
	51

Biermer appears to have found this organ free from lesions in his fifteen cases; and Gusserow, although he mentions slight enlargement of the spleen in his cases, says it presented no characteristic changes of its pulp. In one of Pepper's cases, the spleen was enlarged by one-half; "its pulp was dark and much softened," without leukæmic lesions. In the other, it was "slightly enlarged;" its pulp "softened and purplish, without any leukæmic patches or enlarged Malpighian corpuscles." "Under the microscope, the field was crowded with small round cells (smaller than the majority of the cells in the marrow), spindle-shaped cells, and very pale red blood globules." Much importance cannot be attached to the softness of the spleen in this case, as it had undergone sufficient decomposition to crepitate when handled. In one of Buch's cases, the spleen was moderately enlarged and of a pale red-brown color; in the other, it was also somewhat enlarged (12½ centimetres long, 6 broad. and 4 thick), of a brown-red color and firm, and its glomeruli evident; in Immermann's single autopsy, this organ was also slightly enlarged and hard. In the only instance in which the spleen was found atrophied, it weighed but thirteen drachms, felt tough and cut with resistance. Its cut surface was pale, and the microscope proved an absence of pulp cells and blood corpuscles and a preponderance of trabeculæ and of nucleated fibre cells.

It cannot then be affirmed that this important blood gland, the *spleen*, usually presents any abnormality, much less any special lesion in pernicious anæmia.[1]

4. A similar remark may be made respecting the *lymphatic glands*. In the fifty-one autopsies, their condition is not mentioned sixteen (16) times; they presented no lesions thirty-three (33) times (including Biermer's and Gusserow's 20 cases), the mesenteric glands were "pretty generally enlarged" in one case; and in the remaining one the same glands and the lumbar were unusually small, as if atrophied. The last was the case in which the spleen also was atrophied. In it also one gland only in the body, an axillary gland, was found slightly enlarged.

Condition of lymphatic glands not stated in	16
No lesions in	33
Mesenteric glands generally enlarged in	1
Mesenteric and lumbar glands unusually small in	1
	51

5. One other lesion of great importance remains to be noticed. Prof. Pepper, in 1875, on examining one radius of his last case of progressive anæmia found the marrow "to be made up almost entirely of granular cells," which he considered as due to the hyperplasia of the marrow with production of lymphoid cells—a change described by Ranvier in

[1] Disease of the spleen, no doubt, may be a cause of anæmia, just as disease of the other blood-glands and lungs may be.

1867,[1] and by Neumann and others subsequently, as existing in some cases of leucocythæmia. Dr. F. Fedé, about the same time as Pepper, described similar alterations of the marrow of the bone, in a case which he published as one of progressive pernicious anæmia, but which, as already stated, owing to the accompanying alterations in the spleen, is rather an example of pseudo-leukæmia. This year Dr. Scheby-Buch examined the radius in a case of pernicious anæmia, and found the marrow of a pale-red color, and containing a few fat cells, single drops of fat here and there, and numerous cells in groups resembling white corpuscles, and only a few red corpuscles. On the other hand, in the latest recorded case, M. Lepine found no affection of the bone-marrow. The bones were not examined in the other forty-eight cases, so that the frequency with which this little-known lesion may have existed in them cannot be even surmised.

The import and nature of the change itself are scarcely settled. It has been observed in several cases of leucocythæmia, and in a few of pseudo-leukæmia. Dr. Horatio C. Wood, Jr. (of Philadelphia),[2] examined the long bones taken from patients dead of various chronic diseases, and only in one instance found any abundance of leucocytes in the marrow, and in that one there coexisted marked general enlargement of the lymphatics, and of the spleen. Circumstances prevented a complete examination of the case, so that it may also have been one of leukæmia or pseudo-leukæmia. He thinks it not improbable that the lesion occurs in scrofulosis and in chronic or even acute pyæmia; and I am indebted to my friend, Dr. Osler, Professor of the Institutes of Medicine in McGill University, for the details of an autopsy which he recently made upon a man who died of tuberculous peritonitis, in which the marrow of the femur, the only bone examined, was found to have suffered these changes. Passing over the notice of the case and of the condition of the periosteum found after death, I will relate only his description of the bone-marrow.

"*Medulla.* Upper half of left thigh removed for examination. On section of the bone, the medulla presented a uniform grayish-red color, nowhere having the yellowish fat-like aspect of normal marrow. In the cells of the cancellated portion the marrow was of a lighter red color.

"*Red blood-corpuscles.* A very evident difference in size existed in these elements, very many of which measured $\frac{1}{4500}$ of an inch in diameter; a few were even smaller. Curious irregular forms were numerous, due to the protrusion of portions of the stroma of the corpuscle. Nothing special was noticed about their color or general characters.

"*Colorless corpuscles.* These elements outnumbered considerably the red corpuscles in all the specimens examined. Three or four varieties were noticed: (1) Corpuscles agreeing in general characters with those of the blood; protoplasm firmly granular, nucleus vesicular, variable in number, ranging from one to three or four. Many of these were larger than ordinary white blood-corpuscles, and the nuclei were evident without the addition of any reagents. (2) Somewhat smaller corpuscles with coarsely granular protoplasm and one or two vesicular nuclei. They were not very abundant, and corresponded closely with the coarsely granular corpuscles which are sometimes met with in the blood. (3) Corpuscles with clear vesicular bodies and solid nuclei, usually only one. These were not very numerous, three or four only occurring in the field of the No. 9 (immersion). (4) Small bodies like free nuclei, protoplasm finely granular. These correspond closely with the nuclei

[1] Vide Jaccoud, Nouveau Dict. de Méd. et de Chir., t. xx. p. 430.
[2] Am. Journ. Med. Sci., Oct. 1871, p. 376.

of the former variety, and are probably identical with them, having been freed by the rupture of the cell. Of these varieties No. 1 was by far the most abundant.

"*Transitional forms.* Nucleated, colored corpuscles were noticed in each specimen examined, as many as three or four occurring in the field of the No. 9. They ranged in size from $\frac{1}{3000}$ to $\frac{1}{2500}$ of an inch; the majority of them being slightly larger than the ordinary red corpuscle. The nucleus in every instance was single, and the protoplasm finely granular. Three corpuscles were seen with the nuclei dividing. The coloration of the cell substance was in each case very distinct, and only exceptionally was it less distinct than in the surrounding colored elements.

"*Cells containing red blood-corpuscles.* Two or three only were observed; in one case an ordinary white corpuscle contained a single red corpuscle and two nuclei; in another a somewhat irregular protoplasmic mass contained three red corpuscles and one distinct nucleus. None of the ordinary myeloid or giant cells were found."

In this case of tuberculous peritonitis, then, there existed the changes in the bone-marrow, which have been observed in so called myelogenous leukæmia, and in Pepper's case of pernicious anæmia.

It is not logical, in the present state of knowledge, to conclude that a condition of the marrow which has been found in so many different affections, as leukæmia, Hodgkin's disease, pernicious anæmia, and tuberculous peritonitis, is a pathological state essential to those affections. Moreover, quite recently, Dr. Moxon,[1] of Guy's Hospital, and more recently still, Dr. Schtschastny, of St. Petersburg,[2] have maintained that the bodies resembling white corpuscles found in the bone-medulla in leucocythæmia "were in reality leucocytes which had escaped from the blood." Even if it were true that the condition of the bone-marrow in question was constantly present in pernicious anæmia, the bearings of the fact upon the nature and origin of the disease would remain to be worked out, as physiologists have not altogether accepted the views of Neumann and Bizzozero, that in the adult the medulla of bones is concerned in the development of the white corpuscles of the blood (Flint, Virchow, and others). It is worthy of notice that the two cases of pernicious anæmia in which the medulla was found in a morbid state were complicated, and such as could scarcely be called by the original name of the disease, "idiopathic anæmia." Pepper's patient, aged fifty, had suffered from an obstinate form of psoriasis for twelve to fifteen years; from follicular catarrh of the intestines for twenty-five years; and from the want of nearly all his upper teeth for twelve years before his death, and would not wear false ones. The autopsy revealed not only changes in the medulla of the bones, but chronic suppuration of the gall-bladder, enlargement of the solitary glands of the intestines, and enlargement of the spleen. Scheby-Buch's patient had been sickly for several years, and the autopsy discovered, in addition to disease of the marrow, chronic inflammation and dilatation of the bronchi, and a somewhat enlarged and firm spleen.

I will make only one observation upon the diagnosis of the disease. Quite lately, Dr. H. Eichorst[3] has affirmed that the disease may be *certainly* diagnosed in the early stages from the microscopic characters of

[1] Lancet, May 4, 1876.
[2] Petersburger Medicin. Wochenschrift, No. 20, 17 Juli., 1876.
[3] Centralblatt, Berlin, Juni 24, 1876.

the blood. He says some of the red globules are of normal size, but very pale, and have lost their tendency to form rouleaux; others scarcely attain one-fourth the diameter of a normal perfect corpuscle, so that they look like drops of fat tinged red, and have lost their biconcave appearance. As the disease advances, these "red drops" or foreign elements increase in number; so that before death he has found them as numerous as the intact red corpuscles. The white corpuscles are always in small number.

The diagnostic character here insisted on, viz., the presence in the blood of red globules of much smaller size and paler color than natural, has not always been found according to the few accurate reports made in recent cases. The red globules were observed to be small and pale in one of Buch's cases. In Bradford's case, in which the blood was specially examined, while "there was not much variation in size between the individual globules, all were rather smaller than usual; there was not much detritus." The "white corpuscles seemed to be abnormally granular, and were irregular in shape." In one of my cases (Mr. T——) Prof. Osler noticed "a somewhat unusual variation in size amongst the red globules. Many of them scarcely measured $\frac{1}{5000}$th of an inch in diameter; the white also presented slight variations in size, and were more granular than normal, and Max Schultze's granular masses were abundant."

On the other hand, Prof. Pepper carefully examined the blood in one case, and makes no mention of this variation in size of the red globules, which he describes as "pale, and less biconcave than normal," and adds, "no abnormal elements were seen." And Pye-Smith reports in one case, three weeks before death, that "the colored elements of the blood are not evidently changed either in number or characteristics, but they form no rouleaux."

It should be borne in mind, too, that M. Laptschinsky, of St. Petersburg,[1] has described precisely similar alterations of the blood in various diseases in which marked febrile symptoms obtain, with the addition, however, of an increase in the number of white corpuscles.

It may be that the characters of the blood described by Eichorst are, when present, highly suggestive of pernicious anæmia, but they do not appear to be always present in that affection, and further investigation of the subject is needed before accepting that author's confident statement.

I must conclude this paper, already too long, without an examination of the relations existing between pernicious anæmia and Addison's disease, leukæmia, pseudo-leukæmia, and purpura hæmorrhagica, or of the part taken by the sympathetic system in the production of the blood-changes. Time will not permit of such an undertaking.

The conclusions that I venture to draw on this subject are:—

I. That all the various forms of anæmia, *i. e.*, forms as determined by the conditions under which they occur, may occasionally take on progressive and pernicious characters.

II. That such is not unfrequently the case with the anæmia of pregnancy and parturition, while the converse is true of chlorosis.

III. That it has not been proved that there is a distinct variety of

[1] Lancet, Oct. 31, 1874, p. 157.

anæmia, having an etiology and pathogeny peculiar to itself, and demanding the name "progressive pernicious."

IV. That neither the spleen nor the lymphatic glands usually present any, much less any special, lesion in pernicious anæmia.

V. That it remains to be proved that hyperplasia or other change of the bone-marrow, is a cause of anæmia.

VI. That if it be a cause, it has yet to be shown whether it is the cause of a variety that should be especially styled pernicious and progressive, and that at present the weight of evidence appears to be opposed to that view.

VII. That it is premature to regard pernicious anæmia as a myelogenous pseudo-leukæmia.

VIII. That while pernicious anæmia is perhaps rather more frequent in females than in males, the difference in the liability of the sexes is not very great. Omitting Biermer's 15 cases, the majority of which belonged to the female sex, there remain in my table 47, of which 20 were males, and 27 females.

IX. That with the view of obtaining information as to the nature and causation of the defective hæmatosis in all cases of anæmia, and especially fatal cases, it is necessary to obtain a careful history of the patient's previous health and that of his family, to investigate the progressive changes that take place in the blood and urine as the disease pursues its course, and to examine *post-mortem* the condition of the bones and their marrow, as well as of all the other organs of the body.

Table showing some Details of Sixty-two Cases of Pernicious Progressive Anæmia.

Author.	Date.	Cases.	Sex. M	Sex. F	Age.	Autopsy.	Viscera.	Spleen.	Glands.	Liver.	Heart.	Kidneys.	Blood.	Marrow of bones.	Previous condition of health. Remarks.	Duration.

ALCOHOL IN ITS THERAPEUTIC RELATIONS AS A FOOD AND AS A MEDICINE.

BY
EZRA M. HUNT, M.D.,
OF METUCHEN, N. J.

We propose to consider the subject of this paper[1] by inquiring into—

I. The value of alcohol as a food;

II. Its value as a medicine;

III. How far its value is modified by variability in the composition of spirituous liquors.

I.—Any article, to rank as a food, must be convertible into tissue or force, in such a way as to contribute to healthy vitality and aid the body in the performance of its normal functions. This includes that energy which the body needs in the execution of its own processes of nutrition and repair, and that which must be generated to fit it for the expenditure of proper force in its contact with the world about it. So definite is the relation between the human system and the usual foods by which it is sustained and propelled, that in respect to most of them we are not left in doubt. If we take any one of the ordinary aliments, and subject it to chemical analysis, and then apply the same process of examination to human material, we are not slow to trace the correspondence of the two. Since chemistry has come to be more perfect in its methods of analysis, and physiological investigators have been careful to study relations, and test them by science and art combined, these adaptations are seen to be systematic and definite.

[The ascertainable qualities which constitute a food are, in the original paper, illustrated by a comparison of the various aliments with the organic constituents of the body. A description is given of the ascertained processes of their conversion into tissue and force. The testimony of Wanklyn, Fowne, Attfield, Bridges, Liebig, and Bernard is adduced as to the accuracy of our knowledge of foods, with allusions to the experiments and testimony of Voit, Bischoff, Wilson, Playfair, Lankester, Frankland, Haughton, Mapother, and others. It is shown that alcohol, as subjected to such tests, fails to establish itself as a food.]

There has been such unanimity of consent among those of divergent views in other regards, as to alcohol, that it is not a tissue-building food, that it is by quite common consent excluded from this class. We have never seen but a single suggestion that it could so act, and this a mere guess. One writer (Hammond) thinks it possible that alcohol may somehow enter into combination with the products of tissue decay, and "under certain circumstances might yield their nitrogen to the construction of new tissue." There is no parallel to this in Organic Chemistry, nor can any evidence be found in Animal Chemistry to surround this guess with the aureola of a possible hypothesis.

It has been conclusively proved, says Lionel Beale,[2] that alcohol is not

[1] [The entire paper being too voluminous for insertion, the author has furnished a synopsis for the Transactions, reserving the right to publish the whole in a separate form.—EDITOR.]

[2] Med. Times, 1872.

a food, and does not directly nourish the tissues. "There is nothing in alcohol with which any part of the body can be nourished."[1] "It is not demonstrable at present that alcohol undergoes conversion into tissue."[2] Alcohol contains no nitrogen; it has none of the qualities of the structure-building foods; it is incapable of being transformed into any of them; it is therefore not a food in the sense of its being a constructive agent in the building up of the body.[3] The food tables of Letheby, Frankland, E. Smith, etc., give no place to alcohol as a tissue-forming food, and only allude to ale and porter as containing some nutritious elements from the presence of other substances. The period of youth is that in which it should be used to give muscular development and structure-building power, if possessing these properties, but authors and experimenters with one accord exclude it from the diet of children.

In Comparative Histology we find the structure of animals, and the laws of growth, repair, and tissue-secretion, quite similar to those in man: yet none of the careful experiments as to foods, or the development of the animal kingdom, have ever given alcohol a place for the construction of tissue. This undoubted exclusion of alcohol from nitrogenous foods is all the more significant because recent investigations have shown that this class of foods not only makes cells, but that it has very important correlation in heat producing processes.

[Why alcohol cannot be placed amid carbonaceous, or heat or force producing foods. It is now shown how uniform is the production of heat or force as the result of the union of oxygen with the carbons; how accurately it can be tested, and how alcohol fails in this test. The accuracyof experiments illustrated by those of Pettenkofer, Fowne, etc., with confirmatory quotations from Liebermeister, Edward Smith, Parkes, and H. C. Wood, Jr., showing why alcohol fails as a producer of heat and force.]

The idea that alcohol is a heat-producing food, and so, like calorific foods, is consumed in the system according to the usual law of disintegration, has been so far accepted that Anstie, speaking of its *anti-pyretic* effect, as now admitted, says, "Until within the last few years it was never even suspected."[4] In his advocacy, while claiming that somehow alcohol must be oxidized and converted into force, he then says "this force cannot be heat." In other words, the most remarkable exception in all the laws of energy must be assumed to exist in order to make tenable the view that alcohol undergoes oxidation, so as somehow to elaborate life force. Yet as H. C. Wood, Jr., in his recent work on Materia Medica, expresses it: "No one has been able to detect in the blood any of the ordinary products of its oxidation."[5]

[Examination as to whether alcohol increases the excretion of carbonic acid (carbon-dioxide), which is a leading proof of the food value of the hydrocarbons, of oils, and of such liquids as in their change impart vital force. It is shown that "the quantity of carbon-dioxide and water produced" in vital processes is as accurately determined as in inorganic analysis. Testimony of the leading experimenters examined and compared. The "weight of evidence is that it diminishes the elimination of carbonic acid" (H. C. Wood, Jr.). So far from combining in any way so as to form water, alcohol is the great parcher of tissue. It is inquired next "Is not the formation of fat a result which proves a nutritive process, and is it not secured by the use of alcohol?" Whatever may have been the results from malt liquors, or from sugary or other mixtures containing alcohol, it is shown that alcohol neither contains any fat material, nor is any conversion of it into fat, such as takes place with some foods, ascertainable. Explanation of cases of increase of fat while liquors are used. Remarks as to how imperfect a test of healthy nutrition, is mere increase of fat. Examination of facts as to the reappearance of alcohol in the secretions, and how far its quantitative

absence is a test of its appropriation as a food. The imperfection of the evidence as shown by a survey of the experiments and views of Anstie, Ford, Parkes, Thudichum and Dupré, Richardson, Duroy and Massing, Ringer, etc.]

Parkes says, in reply to Anstie,[1] "Even if complete destruction within certain limits were quite clear, this fact alone would not guide us to the dietetic use of alcohol. We have first to trace the effect of the destruction, and learn whether it is for good or for evil. You seem to think that the destruction must give rise to useful force, but I cannot think that this is necessarily so." When an article appears to a considerable extent in the excretions, it seems to indicate at least that it is not readily assimilated. If under experiments absolutely complete, instead of very defective, alcohol could not all be found, we would look for such results of disintegration as the laws of animal chemistry would indicate, and see how the changed products had been made available as food. Finding none of those products which are derived from alcohol as consumed out of the system, nor such as occur when foods are appropriated in the system, we would be quite excusable for asking some evidence of food-value beyond the fact that the exact quantity imbibed could not be recovered from the excretions.

We can find no chemical law or practical excretory result which defines alcohol as a food. "The mode of destruction is in fact unknown."[2] We search in vain for products of oxidation, except a slight change perhaps of a portion into acetic acid, in the stomach, and, in the case of the imbibition of large quantities, the acidity of the urine which is found slightly increased. "Yet in animals poisoned with alcohol, Buckheim and Massing could find no acetic acid in the blood."[3] No one has as yet been able to show a method of consumption such as ought to be manifested if this article acts as a food. If decomposed at all, it is, says Richardson, probably "at the expense of the oxygen which ought to be applied for the natural heating of the body."

But if those who would defend alcohol as a food are unable to identify it as such by any of those tests which indicate nutritive or energizing foods, may we not assign it a place in what are called accessory or auxiliary foods?

[Accessory and auxiliary foods defined, and the terms shown not to be an indefinite escapement for failures of evidence. How as a so-called accessory or auxiliary food alcohol fails to find for itself such a place as is assigned to water, chloride of sodium, condiments, fruits, etc. It is shown how modern chemistry has made even those which we once called accessory foods to have a definable place.]

Alcohol not only does not merit a place as an accessory food, according to any known laws of such foods, but it is very well known to induce deterioration of tissue, and to disturb the relation between the nitrogenous foods and water. In appropriating the water so as to dry the tissue, as already noted, it thickens membranes intended for that vital transmission of fluids known as endosmose. Thus local "sclerosis or a hardening of nerve tissues is one of its frequent manifestations."[4]

[Special examination of the attempt to define alcohol as an accessory food by saying that it delays metamorphosis of tissue. The whole subject of progressive and retrogressive metamorphosis of tissue examined. Their importance as physiological processes shown to be such that delay of metamorphosis is in itself, as a rule, a disturbing and invaliding process. It is so exceptionally beneficial that it must be directly shown, in the case of any special medicament, that it is conservative of health, and how it is. Quotations from

[1] Practitioner, p. 85.
[2] Parkes, p. 272.
[3] Ibid.
[4] Hammond.

Pappenheim, Cameron, Beale, Hammond, and others, showing the inconclusiveness of this kind of evidence. Full examination of this argument as attempted to be substantiated by diminution or change in excretions, and by its impeding of corpuscle and other blood-changes.

Examination of the claim that alcohol belongs to the catalytic substances, and modifies metamorphosis by the "action of presence."

Next, does alcohol show a food value by the tests of dietetic and sanitary experience? Examination of the cases of Anstie and Inman, and rebutting evidence. It is concluded that alcohol is not shown to have a definite food value by any of the methods of chemical analysis or physiological investigation.]

II.—We next propose to discuss the place of alcohol in the Materia Medica, and its therapeutic action. "There is," says Lionel Beale, "no more important question in medicine to be determined than the action of alcohol in disease." As we come to inquire into the value of alcohol as a medicine, after having found its reputation as a food unsustained, it is well to remember that the terms food and medicine are often more nearly allied than the mention of the words is apt to indicate. A medicine is that which helps to heal or repair, for that is both the etymological meaning of the word and the practical design of the article used. The process of restoration or repair is often but an application of the process of natural nutrition. Amid the progressive changes of food into tissue, and the retrogressive disintegration which all life implies, we must not deceive ourselves by terms. Much of the discussion, therefore, as to the value of alcohol as a medicine, is in reality to be determined by what it can do toward repairing the waste of tissue which occurs in disease. What it can do in this regard depends largely upon the determination of its food value. This we have seen to be so small and indeterminate, that it will not do to push it forward as a valuable medicine in those respects in which medicine chiefly concerns nutrition and the production of animal heat.

When we find that alcohol has no nitrogen with which to nourish; that it does not respond to the laws by which animal heat is usually evolved; that it at best undergoes such imperfect change in the system that much of it is found unchanged in the secretions, excretions, and tissues; that the products of its primary or secondary change cannot be identified; that it is not settled whether it diminishes the carbonic acid, or urea, or other excreta, or whether such diminution would be reparative, we may well hesitate to assign this drug a place in the category of medicinal agents. When it has eluded the ingenuities of science, the persuasions of art, and the astute diligence of interest, to extemporize it into a food, it must be remembered that it has made a signal failure to vindicate its position as a medicine in any one of the particulars in regard to which it is most frequently urged as of value.

[Next to the consideration of the place of alcohol as a medicine, we come to inquire how far the variability in the composition of spirituous liquors and their unreliability modify their therapeutic value.]

III.—If we are to consider any article therapeutically, we ought to be able to know that it is the article which it professes to be. The clinician who claims uniformity of result, and a declared therapeutic effect, from a given article, has reason to question whether the effect was a result of the conceived cause, when he finds that the alleged cause was necessarily inoperative by reason of absence or admixture. If the article used was not tested either as to quality or quantity, if the general rule in respect

to it is unreliability, we surely cannot trust general opinions as to its dietetic or medicinal value.

We have been used to hear criticism as to the composition of liquors without much professional impression derived therefrom, supposing that these criticisms were chiefly based upon general accusation, or the trial of bar-room specimens, and that the bonded warehouse and the druggist's label were an assurance of purity. But in the medicinal examination of liquors we find some facts which address themselves to us most directly in their clinical bearings. In our inquiry in this line we shall pursue the same course as when examining into food value, seeking our information from chemists, from medical experts, and from the best accepted authorities on the composition of alcoholic medicines.

There is much difference in different spirituous liquors, and in different specimens of the same kinds of liquor, as to the amount and kinds of alcohol and other ingredients, independent of any question of adulteration. A reference to the Proportion Tables of Brande, Fontenelle, Bence Jones, Thudichum and Dupré, etc., will show at a glance such variations as these: Wines, in general, contain from 8 to 26 per cent. of alcohol; Madeira from 19 to 26 per cent.; Port from 17 to 25 per cent; Sherry from 19 to 25 per cent.; and various other wines from 16 to 18 per cent. Thudichum and Dupré state that a natural wine may contain from 9 to 16 per cent. of alcohol. Fowne says of them, "The quantity of alcohol varies very much." Sherry often has from 6 to 8 gallons, port wine 3 gallons, and the best port 13 to 15 gallons of brandy, added per cask. This is not considered admixture, but original "fortification," as it is called. Native European wines, by the English law, must not have over 26 per cent. of alcohol. Champagne, Burgundy, and the Rhenish wines, contain an amount varying from 8 to 14 per cent., by measure, of alcohol.

Such statements are made still more significant from the authority of Parkes, who says: "So various is the amount of alcohol in wines from the same district, that a very general notion only can be obtained by tables, and samples of the wine actually used must be analyzed."[1] Brandy, whiskey, and gin contain from 50 to 60 per cent. of alcohol, and rum from 60 to 80 per cent.; apple brandy should have from 40 to 46 per cent. As we shall see hereafter, these are so varied in other regards, in the various processes and methods of manufacture, that their more restricted alcoholic variation is an inadequate measure of their therapeutical import.

If, as claimed by most, alcohol is the chief available medicinal ingredient of alcoholic stimulants, it is clinically requisite to know just how much we are administering in each dose prescribed. This all the more when leading representatives of alcoholic treatment now claim that the limit in health is within two ounces in twenty-four hours; and that the limit in disease is far narrower than once believed. In face of the grave facts which come to us from pathology and from practice as to the effects of over-doses on the nervous and circulatory systems, and upon secretion and excretion, it is not good practice to deal with an article without some definite knowledge of the dose administered. While effects are a proper measure of degree of use, when they are so watched and classified, and so numerous, as to justify inferences, yet that must

[1] Op. cit. p. 265.

ever be an imperfect clinical study of any medicine which is unable to state the amount administered in any given case.

But the time is already at hand when, in speaking of alcoholic liquors, we must define what form of alcohol we mean, as well as how much of it is present, since they are often mingled, and their physiological and medicinal effects are totally different. Let us gather up briefly from chemists and experimenters, such as Fowne, Attfield, Richardson, and Prescott, a few significant facts, which are, we believe, not gainsaid, and which present the question of the medicinal use of alcohol, so called, in quite a new light.

Fowne gives a list of twelve alcohols, as belonging to what is known as the monatomic series. Of these, five chiefly concern us in medicinal and dietetic relations; these are the methylic, CH_4O; the ethylic, C_2H_6O; the propylic, C_3H_8O; the butylic, $C_4H_{10}O$; and the amylic, $C_5H_{12}O$. Fowne says: "The term alcohol, originally limited to one substance, viz., spirit of wine, is now applied to a large number of organic compounds, many of which, in their external characters, exhibit but little resemblance to ordinary alcohol." Yet, as we shall see, no usual liquor is clear of some one of them besides the ethylic, which is the one known as common alcohol; and, secondly, their effects are medicinally quite different..

"The first of the series, methyl alcohol, naphtha, or wood spirit, is not an original impurity in manufactures of an ethyl (or common) alcohol; but in the form of methylated spirit has been added in the falsification of liquors."[1] Pure methyl alcohol is a colorless, thin liquid, very similar in smell and taste to ethyl alcohol, and, like it, is a mobile, watery liquid.[2] "It has an aromatic odor, free from empyreuma, and a sharp but not acrid taste."[3] The methylated spirit has been used fraudulently in the manufacture of the sweet spirit of nitre.[4] Richardson[5] has made some important inquiries in respect to this substance. He names the case of a well-known physician who himself used it in preference to common alcohol, regarding it as less injurious. Richardson has long used it in his practice as a substitute for the common alcohol. He says "it is much more rapid in action, and much less prolonged in its effects, than is common alcohol, so that it produces its effects promptly, and, what is of most importance, it demands the least possible ultimate expenditure of animal force for its elimination from the body. This latter fact is of great moment, for, in the end, all these alcoholic fluids are depressants, and although at first, by their calling vigorously into play the natural forces, they seem to excite, and are therefore called stimulants—they themselves supply no force." He notices its special power of reducing the temperature (p. 32), and calls it the lightest and least injurious of the alcohols (p. 23). If we are giving an alcoholic medicine made of this substance, we are using the spirit most allied to, and yet very distinct from, ethylic alcohol, or the purported kind.[6]

The propylic alcohol is not yet much understood in its medicinal action. Chancel[7] obtained it from fusel or amylic alcohol by fractional distillation. One of its isomeric modifications has a very close resemblance to ethyl alcohol. It is not unfrequently found with it in liquors, and, of course, modifies its characteristics. Its medicinal action is not

[6] See also Monroe, "Is Alcohol Necessary?"
[7] Fowne, p. 31.

yet well enough understood to draw the contrast between it and the genuine ethyl drink or medicine. It is, if possible, even more greedy of water than the latter, and so still more robs the tissues.

Butylic alcohol is often contained in amylic alcohol, and so is present in the usual fermentations. When valerianic acid is artificially prepared from butylic alcohol, as is commonly done, the various valerianates are often contaminated by butyrates.[1] There is reason, therefore, to believe that it is often present with the other alcohols. Richardson seems to have shown that this heavier alcohol is much more apt than the ordinary alcohol to cause tremors of the kind occurring in delirium tremens. Its effect is certainly very different from that of the alcohol designed for common medicinal use, and it must be studied by the physician in its own distinct effects.

The next in the series is known variously as amylic alcohol, potato oil, grain oil or grain spirit, and fusel oil. In its relation to the ethylic or assumed common alcohol of alcoholic liquors, it is of most interest to the physician. "It constitutes," says H. B. Prescott,[2] "the chief part of fusel oil, which also contains the fourth alcohol (butylic), and traces of the third (propylic), and these together appear quite invariably in the alcoholic fermentation of sugar, their preparation being varied by conditions." "It is the great and naturally occurring impurity of liquors," says Fowne (p. 535). In the manufacture of brandy from corn, potatoes, or the must of grapes, the ethyl (common) alcohol is found to be accompanied by an acrid oily liquid called fusel oil, which is very difficult to separate completely from the ethyl alcohol." Attfield[3] says, "Amylic alcohol is a constant accompaniment of ethylic or common alcohol, when the latter is prepared from sugar which has been derived from starch." This, of course, applies to all alcoholics prepared from grains or vegetables, either by brewing or distillation.[4] Not only does it thus occur naturally, but some of that found in wines and spirits is probably added. Much of it is imported to England, it is believed, for that purpose.[5] No doubt much of it is thus returned to us as a direct re-importation, marked pure from the bonded warehouse. As common alcohol dissolves it readily,[6] as it has a pungent but not acrid taste by dilution, and has a fruity taste and smell, it is much relished. It is the heaviest and most injurious of the five alcohols thus far noticed. It has a burning, acrid taste, its vapor producing oppression of the chest.[7] When produced as so often in manufacture, or when added for profit and improvement of flavor, it is "an extremely dangerous addition to ordinary alcohol." Its action is the same as that of butylic alcohol, "except more prolonged by reason of its greater weight and insolubility."[8]

In this country, where whiskey and other fermented products are so largely used, the art of their concealment and modification so as to give a relished flavor, is well understood. There is little doubt that certain effects of alcoholic liquors of late years are due to the more profitable utilization of the "contemporaneous" alcohols with the ethylic. It is also true that the addition of such alcoholics as the methylic, or of various substitutes for all the alcohols, has left what is called the experience of prescribers somewhat mythical.

[Next it is shown how, in the various modes of preparation and manufacture, variations occur not only from different vintages, distilleries, and breweries, but from difference in method and the financial interests of makers—all within the limit of legitimate preparation.

Next it is shown, by the testimony of chemists, how different alcoholics are modified by adulteration or imitation. Testimony of Thudichum and Dupré, Mülder, Parkes, Richardson, Battershall, Prescott, Cameron, etc.]

There is still another most important therapeutical view to be taken of the various alcoholics.

The time has already come when prepared liquors which have never seen a vintage or a distillery, dispute their right to be accounted genuine, and not to be branded with the epithet "adulteration." The ablest and most candid French work and authority on the manufacture of liquors (Duplais), discusses the question from the stand-point of business integrity, and leaves it without adverse decision. Prof. A. B. Prescott, the able chemist of Michigan University, in his work on the Chemical Examination of Alcoholic Liquors, says: "The term brandy, as used in commerce, without qualification, must be held by common consent to include artificial brandy." He makes three divisions, viz.: veritable brandy, artificial brandy (or that made of the same ingredients according to chemistry), and fictitious brandy; *i. e.* a fraudulent imitation. There are many preparations known as brandy essences, which are so combined with spirit as to make artificial brandies difficult of distinction from the veritable.[1]

Griffen, who is an authority, and who has examined many specimens, says that he found what he called Public House Brandy not to be a distilled spirit, and yet that it had the taste of a good cognac. He gives a German recipe which he says, after long keeping, gives a brandy very similar to real cognac in taste and odor. He adds that this sort of sophistication is evidently becoming an ordinary commercial practice. The recipe, as given by him, contains much purified spirit, but only eight quarts of wine to 150 quarts of mixture.

Duplais's most able and scientific work, of 700 pages octavo, translated by McKennie, and published by Baird, Philadelphia, 1871, would be incomplete without its pages on "Imitations." Speaking of cognac, as the most difficult of all brandies to prepare artificially, it says (p. 293): "It is a fact worthy of note that the brandy obtained in consequence of the addition of a spirit foreign to the wine, in limited proportions, cannot be distinguished from the natural wine by itself, that is to say, without the addition. Finally, brandy resulting from the new method, defies all methods of investigation. We may suspect the mixture, and even know of its existence, but we cannot furnish the proof; neither the most skilful and practiced taste, nor the persevering researches of the most skilful and learned chemists, have been able to detect it. M. Payen himself acknowledged some time since that, in the actual state of the science, the discovery of the mixture presented insurmountable obstacles." Such a book as that of Pierre Lacour, on "The Manufacture of Liquors, Wines, and Cordials, without the aid of Distillation," and others well-known to makers, and but little to physicians and pharmacists, show to what perfection the experts have attained. The chapter of Duplais on the preparation of various liquors, of which alcohol, sugar, and water, are the basis, also shows how artificial and successful are such compounds. The author, after admitting that "the immoderate use of spirits, and

[1] Prescott, p. 23.

even liquors, is pernicious," and after designating the drunkard as "a wretch who is unworthy to live" (pp. 437–8), claims that the "aromatics and sugar are good for digestion," and the small quantity of alcohol not injurious to persons in health.

We have had occasion to examine recent popular books of recipes for the imitation of liquors, and it is wonderful to what perfection the art has been elaborated. When we look into our recent chemistries and see how many natural products are duplicated in art, and that fruit essences and flavors are so well imitated that connoisseurs cannot distinguish the artificial from the real, it is to be expected that the great profits accruing would induce the production of liquors without the trouble of vintage, wine press, or distillery. More Madeira wine is in the market than could be made on the island of Madeira if each grape made a gallon. Critical examinations have gone far enough to show that in all alcoholic drinks, as consumed for thirst or medicine, the veritable article is largely reduced or superseded by admixtures and imitations. The editor of the London Lancet well says: "We suggest it were well worth our while in the future for us to transfer our allegiance, when we would prescribe alcohol, from the wine and spirit merchant to the chemist."[1] When imitations are repudiating the reflection of being "spurious," and claiming legitimate place beside the "veritable" products, and when the "fictitious" are difficult of distinguishment, is it not high time for the therapeutist to take reckoning as to his professional position in reference to alcoholics as at present prescribed?

In face of facts, such as we have adduced, it is a burlesque on the precision of modern therapeutics to deliver *ex cathedrâ* opinions as to the medicinal value of alcohol, when we are using all sorts of remedies under the name, are attributing to them results which are shown to be impossible, and prescribing them with an unscientific laxity which would be scouted in the confines or even in the purlieus of any exact science or any expert art.

In the light of accumulating facts as to the whole alcohol series, as to the manifold and variable combinations prescribed under the cognomen of alcoholics, and with candid regard to the wide and contradictory range of their composition, we must needs review the record of our materia medica. We must recognize the unscientific and empirical data on which we have rested, as insufficient to overcome the facts of histological and pathological research, and feel that demand is made upon us to show the conservative *modus operandi* of a medicine which so significantly asserts itself as a toxic and depressant.

Such questions as these are presented for exact consideration, to a degree that neither science nor practice would ignore.

(1) What is the effect of ethyl alcohol as a medicine?

(2) What trustworthy experiments have we as to its physiological effects, and as to its therapeutic indications?

(3) What guide as to the quantity to be given?

(4) What testimonies of experience as to its clinical use?

(5) With present light as to the manifold variations of alcohol in legitimate manufacture, and its change by admixture, are the usual testimonies as to the advantage of ethyl alcohol as a medicine of any professional value, unless composition has been determined?

[1] Lancet, Nov. 1, 1873, p. 639.

(6) How far can methyl alcohol take the place of ethyl alcohol as a medicine?[1]

(7) How much does any alcohol or fusel oil occur in various alcoholics, either by virtue of manufacture or admixture?

(8) How far are the effects of wines dependent upon their numerous exhilarating ethers, their albuminous matters, their sugars, acids, and salts, and how far are the effects of each kind due to the varying proportions of these? The same inquiry may be made as to all alcoholics from fruits.

(9) How far is the effect of whiskey due to its ethers, essential oils, acids, sugars, malt, etc., and so as to all distilled liquors from grains?

(10) How far do the effects of malted ales, beers, etc., depend on sugar, starch, etc.?

(11) How much are clinical experiments worth which speak of the value of alcohol as a medicine, with utter disregard of such items?

(12) Is it possible so to deprive wines, etc., of all alcohol, as to secure their action independent of the spirit?

[The rest of the paper reviews the changes in the use of alcohol in various diseases, and shows how assumptions as to its value have been modified. It shows, also, how other exhilarants can easily be substituted in a large majority of cases.]

The following are the conclusions submitted to the Section of Practical Medicine:—

I. Alcohol is not shown to have a definite food value by any of the methods of chemical analysis or physiological investigation.

II. Its use as a medicine is chiefly that of a cardiac stimulant, and often admits of substitution.

III. As a medicine, it is not well-fitted for self-prescription by the laity, and the medical profession is not accountable for such administration, or for the enormous evils arising therefrom.

IV. The purity of alcoholic liquors is, in general, not as well assured as that of articles used for medicine should be. The various mixtures, when used as medicines, should have a definite and known composition, and should not be interchanged promiscuously.

On motion of Dr. J. M. Ridge, of Camden, N. J., seconded by Dr. N. S. Davis, of Chicago, Ill., the conclusions of Dr. Hunt's paper were adopted as expressing the opinion of the Section, and were ordered to be transmitted to the National Temperance Society, the Women's National Christian Temperance Union, and the Friend's Temperance Union of New York, in reply to communications addressed by those bodies to the International Medical Congress, and by the Congress referred to the Section on Medicine.

[1] Richardson says that it is practicable to substitute it. A. B. Prescott expresses the opinion that the views of Richardson are correct. The introduction of methylated spirit, in place of the excise proof-spirit, has been a most important measure in Great Britain. See Report of Professors Graham, Hoffman, and Redwood, Quarterly Journal of Chemical Society, vol. viii., and Fowne's Chemistry, p. 518.

REPORT OF INVESTIGATIONS MADE UNDER THE DIRECTION OF PROFESSOR RUDNEW AT THE INSTITUTE OF PATHOLOGICAL ANATOMY OF ST PETERSBURG.

COMMUNICATED BY
PROFESSOR RUDNEW.

I. Sclerosis of the Vessels of the Lungs.

By Dr. Beresnewitsch.

Many eminent writers maintain that the vessels of the lungs are subject to a disease known as "Sclerosis," or the "Atheromatous process." Dittrich, in his work entitled "Uber den Laenneckschen Lungeninfarct," especially describes this disease, and states that it affects the arterial branches of the lungs, and causes the formation of a substance within the inner and middle coatings of the vessels, which he further asserts becomes, in time, either a fibrous tissue, or fatty or calcareous matter. Dittrich further says that this affection occurs more frequently with cardiac disease, especially of the right ventricle, or when the lungs are themselves affected with atrophy and emphysema.

Far from agreeing with this authority, we are led to believe from more recent observations, that instead of sclerosis resulting from emphysema, emphysema is more probably due to sclerosis. Other writers and anatomists seem to have given but little attention to this form of lung disease, some being disposed to accept Dittrich's theory, while others maintain the opinion that sclerosis of the lung vessels is extremely rare. In consequence of the small number of careful observations made in respect to this disease, and the diversity of opinion which appears to exist, I have instructed Dr. Beresnewitsch, one of my pupils, to determine by the minutest microscopical observation, (1) what arteries are directly affected (whether bronchial or pulmonary), and (2) under what conditions this disease occurs, the latter question to be investigated before the former.

Dr. Isaacson, one of my pupils, some years ago investigated, under my direction, many cases of emphysematous degeneration of the lungs, and found that this disease was always due to an affection of the lung vessels. The development of emphysema begins when the bloodvessels become closed by coagula, around which the tissues disappear by reason of want of nourishment. The occurrence of this coagulation is due to the destruction of the inner coating of the artery, and now Dr. Beresnewitsch has shown that this destruction is due to the presence of syphilitic infection, which in course of time manifests itself not only in the capillaries but also in the larger vessels, sclerosis consisting in the development of connective tissue between the layers which form the inner coating of the artery.

II. On the Development of Cancer in the Lymphatic Glands.

By Dr. Afanasieff.

Cornil, Thiersch, Waldeyer, Rudnew, and others, by their investigations, have already proved that the primary development of cancer always originates from the morbid condition of true epithelium. The greater part of the writers of the present day agree with this opinion, while the number inclined to differ therefrom becomes gradually less and less. The minute and careful investigations of later days tend to confirm this view, as we hear of no cases at the present time, in which cancer is reported as arising otherwise than in the epithelium.

This theory has been based upon the fact, only lately discovered, that there are many new formations which have hitherto been considered as cancerous, but which, although very similar, are not cancers at all, but tumors which are called endotheliomatous, a term which perfectly separates them from cancers which are epitheliomatous.

Upon the secondary knots of cancer, the opinions of different writers do not accord—some affirming that the secondary formations actually arise from the passing of cellular particles from the primary growth, while others maintain that the cellular particles transferred, impregnate those already existing, and thus together lead to the formation of the secondary knots. Waldeyer, Lücke, and a few others, accept the former view, but refuse to accept the latter. These authorities appear to base their opinion upon the doctrine of Remak, who asserts that the cells of the upper and lower layers of the embryo never mix with the elements of the middle layer.

In conjunction with my colleagues, I have lately undertaken a careful examination of the lymphatic glands affected with secondary cancer, and we find that, whether the glands are sound or affected by previous morbid processes, the condition of development of cancer knots remains the same, and in either case is due solely to the cellular particles transmitted from the primary cancer, and does not in any way result from the already existing elements of the glands, which elements, far from participating in the formation of the cancer knots, undergo a retrogressive change.

III. Pathology of Sclerosis of the Arteries.

By Dr. Engelhard.

The morbid changes to which the arteries are subject have been known a long time. Crell, Haller, Morgagni, and other writers of past times, described thickness and ossification of the arterial walls, but they did not possess the means now brought to bear in investigation, and seem to have considered the different stages of the disease, not as we now understand them to be, various phases of the same affection, but as totally distinct morbid conditions. The opinion of the authors referred to, upon the causes of disease of the arteries, seems to have been vague and contrary to fact, inasmuch as they attributed this form of disease to the absorption of foreign matter previously infused into the blood. Lebert and Stokes are, however, of opinion that sclerosis of the arteries arises from local changes produced by the nutrition, while Rokitansky, who formerly adhered to his own theory that the disease was due to the

deposit of a certain substance from the blood, now agrees with Dittrich and Virchow in attributing its origin to abnormal extension of the arteries.

With these three distinct forms of opinion, at variance with each other, which is to be considered as the correct one? The recent investigations made by myself and colleagues tend to convince us that not one of the already stated views is according to fact.

We find that the first morbid appearance is due to a rupture of the media which permits a passage from the adventitia to the intima. This rupture causes irritation of the adventitia, and provokes inflammation, the products of which pass through the seat of rupture and propagate within the intima. This rupture, crevice, or cleft, as it may be termed, although probably of minute dimensions at first, is greatly influenced by the amount of the product of inflammation, so that, as that product increases, so also does the crevice become increasingly large, until in due course the media in certain parts are totally destroyed, and the regular circulation of the blood is markedly obstructed, thus giving rise, after a time, to the various forms of aneurism. This will explain the manner in which sclerosis and aneurism of the arteries originate in certain cases.

Another form of the disease may be regarded as arising, not in consequence of an affection of the media, but of the intima itself. The internal surface of the intima ceases to retain its natural smoothness and rotundity, becoming undulating in appearance from an irregular thickening of its tissues, which thickening gives rise to *scores*, the ulceration of which, being permitted to increase, involves in destruction first the media and afterwards the adventitia. When the destruction of the media is complete, aneurism soon follows.

Having thus classed the forms of this disease under two distinct heads, permit me to specify the several causes by which they are produced. The first and most frequent cause of the changes of the vessels may be considered to be syphilitic infection of the body; the tissues of the media, under a syphilitic influence, being extremely fragile and liable to be ruptured from distension. Another very frequent cause is found in the morbid effect produced by alcoholic drinks. I may mention in reference to these two causes, that the first or syphilitic affection generally attacks the media, while the influence of alcohol is found to affect chiefly the intima. Among the many other causes of the production of sclerosis of the arteries, is the absorption of certain poisonous substances, such as mercury, phosphorus, etc., as well as of those poisonous matters the chemical nature of which is but little known, as those of typhus and intermittent fever, etc.

Now permit me to describe the anatomical changes, microscopical as well as macroscopical, to which the coats of the bloodvessels are liable. The *macroscopical* changes consist in a local thickening of the intima, having the appearance of yellowish spots dispersed over the inner surface of the arteries. The next stage or change is confined to the enlargement of the artery until it reaches the condition of aneurism. In describing the *microscopical* changes, I would distinguish very clearly the two different changes in the coats of the vessels. In the first or syphilitic affection the disease begins with a rupture in the media, which permits the inflammatory product of the adventitia to pass to the intima. This inflammation has generally the character of granulated inflammation. The second form commences, on the contrary, in the intima, the first

change consisting in the appearance of minute cellular particles collected into nests of a size more or less large. These cellular particles arise from two sources; sometimes they are formed by division of the tissue-cells, but more generally their existence is due to the extravasation of the white blood-corpuscles. These nests do not long retain their form, but in consequence of the degeneration of the cells are transferred into scores, giving rise to the Endarteritis ulcerosa.

THE MICROSCOPY OF THE BLOOD.

BY

CHRISTOPHER JOHNSTON, M.D.,
OF BALTIMORE, MD.

A DISTINGUISHED writer, Dr. Thomas Williams,[1] states that "in the category of the nutritive fluids unmixed fluidity is not known; solids are introduced. Fluids are not self-productive; they require either the direct or the catalytic agency of solids. The fluids even of the vegetable organism bear floating corpuscles." And again farther on he insists that "no single real example occurs in the whole animal kingdom of a nutrient fluid totally destitute of morphological elements. This rule (of the corpusculation of the animal fluids) is ultimate and absolute."

The blood proper, corpusculated therefore, the chiefest of nutrient fluids, differs from any other, both in vertebrates and invertebrates, in that it is contained in a closed system of vessels, and moves in a determinate circulatory orbit. It was "this circulation, the discovery of which does not, and could hardly," says Flourens, "belong to one man, or even to a single epoch. Galen opposed Erasistratus; he opened the way which, afterwards followed by Vesalius, by Servetus, by Colombo, by Cæsalpinus, by Fabricius of Acquapendente, led us to Harvey." Whilst naming the great Servetus, however, we ought possibly to have cited another Spanish claimant, Francisco de la Reyna, of whom Don Francisco Benito Jeronimo Feyjoo (a very eminent and learned man, who "did more for the intellectual life of his country," observes Ticknor,[2] "than had been done for a century"), in the third edition of his "Cartas Eruditas," published in Madrid in 1774, makes the following mention. In the twenty-eighth Carta he says: "The literary phenomenon which you bring to my notice is rare, and curious as rare. Is it possible that

[1] British and Foreign Medico-Chirurgical Review, Oct. 1853, p. 361; Art. I., The Blood, etc.

[2] Ticknor's History of Spanish Literature.

a Spanish farrier can have been the first discoverer of the circulation of the blood? You write me that a friend of yours has a Book of Farriery, by the Farrier Francisco de la Reyna, printed in Burgos in the house of Felipe de la Junta in the year 1564, and that he saw the fellow to it in the Royal Library, probably the only copies in Spain. You send me the transcript of a passage in Chapter 94 of the said volume, so clear, so decisive, as to the circulation of the blood, that it establishes the fact that the aforesaid Reyna was acquainted with it. This little sentence banishes all doubt: "*So that the blood goes round and circulates throughout all the members* (De manera que la sangre anda en torno, y en rueda por todos los miembros)." Or, as Feyjoo, on page 318, quotes, "our Farrier, who first, before Harvey, used the word *circulation*,[1] and who left it distinctly written that the blood goes round and circulates through all the members (la sangre anda en torno y rueda por todos los miembros)."

However this may be, the circulation of the blood, the passage of the blood from the arteries into the veins, was *proven* as a fact by Harvey, but the direct demonstration was wanting. It came at last, the microscope afforded it; yet it was denied to the grand old age of Harvey, who died without witnessing it. But in 1661 Malpighi *saw* the blood pass from the arteries into the veins of the mesentery, the lung, and the urinary bladder of frogs, and by that act crowned the work

"By the side of the Wolffian bodies, on the axial side, the general epithelial lining of the great lymph sac, the pleuro-peritoneal cavity," thickens, its cells assume a columnar shape, they proliferate freely, and then form a raised mass of "germ epithelium." "From this layer the ova are subsequently developed, whilst the vascular stroma of the ovary is formed by an outgrowth from the side of the Wolffian body." In these few words a modern writer, while noticing the advanced genesial labors of Dr. Foulis,[2] expresses upon certain points the common belief of embryologists, and points out, in terms which they may or must accept, the manner of a new departure of nucleated protoplasm in the production of "primordial ova" from the germ-epithelial corpuscles. And again, according to Schenck,[3] we assert that "originally the entire pleuro-peritoneal fissure is lined on its inner surface with cylindrical cells, which originate from the subdivided lateral portions of what was at first the middle germinal plate." And this layer of cells serves exclusively to form the subsequent peritoneal epithelium. But the cylinders soon disappear, leaving as their descendants entirely flat, pale elements; the median angle corresponding to Remak's middle plate, and later the Wolffian bodies, which grow out from this spot, alone retain their covering of cylindrical epithelium. Since then this peculiar cylindrical epithelium, this germ-epithelium, gives rise out of its own elements to the primordial ovum, it follows that all tissues whatsoever reckon these extraordinary elements as their ancestors; and that, whatever be the intermediate forms, the transition is neither sudden nor remote from cylinders of germ epithelium to the corpuscles of the blood, that fluid organ of which it is now our province to speak.

The microscopical study of the Blood, however fascinating, is beset with difficulties even if we confine ourselves to the human subject, and

[1] Error: "Huic sanguinis *circulationi* ex dextro cordis ventriculo per pulmones, etc." Andreas Cæsalpini Quæstionum peripateticorum, lib. v. p. 125. Edition of the Giuntas, Venice, 1593.

[2] Lancet, March 14, 1876.

[3] Stricker, p. 540, Beitrag, etc.

these are greatly increased if our observations extend to other animals which are spoken of as standing lower in the scale. Its state or condition as deprived of life, its constituent parts motionless and tending to decomposition, must be regarded, or else it must be studied in the energy of life as it hurries on in the performance of its errand, making its circuit, and coming again and again to the *primum moventem;* as the sweet bard of Avon spoke of "those ruddy drops which visit this sad heart." Nor is the blood simply alive, it is also the seat of life; it is life itself. "Vita est in sanguine, vita est sanguis ipsa." Again the blood may be studied microscopically or otherwise, as an organ self-sustaining, replenishing its substance, providing for its own nutrition and loss by wear; as an organ, "mère de tous les tissus,"[1] offering to every structure the pabulum for its needs; as an organ, through or by its anatomical constituents, brought into intimate association with the great acts of nutrition; and as an organ gathering up the molecules of somatic attrition everywhere and conveying them to an emunctory. The blood also offers for consideration various accidental, incidental, and temporarily abiding matters, such as therapeutical remedies, introduced by the mouth or by the hypodermic needle; poisons of every kind; bacteria, on the high authority of Billroth and others; and Filaria sanguinis, as seen by many in the blood of dogs, but studied in India, in the human blood, by T. R. Lewis, M.B., and by him associated with that singular condition of which chylous urine is a marked feature.

The elements of which this exceedingly composite fluid is made up, in the vertebrata, may be arranged in several categories, *one* of which would include all of the many components, whether tending centripetally or centrifugally, whether these be a solvent, or be themselves held in suspension or solution, and all regarded and scrutinized in the state in which they absolutely exist in the blood; *another* would segregate the same elements, and present them isolated, each in its own distinct and independent physical condition; and finally *a third* would establish a distinction between the elements having form and those having no definite figure, or being formless in their actual mode of being in the living, moving, sanguineous stream.

It is true that the microscope must be the handmaiden of science in each of these fields, limitrophic but yet autonomic, whether the objects be originally, primarily, or secondarily encountered in them; but it is with the elements of the *third category* that the microscope chiefly exhibits and exerts its magical power, presenting to the eye, "and to the intelligence by the eye,"[2] life-histories of the forms which swarm in its illuminated circle, whether the tendencies be intrinsic or extrinsic, normal or pathological. The elements which have a form, characteristic and determined, and an approximative size, are the red corpuscles and the leucocytes, white corpuscles, or white globules; and with these we propose to deal exclusively, regarding them from two points of view, viz., (1) that of anatomy and physiology, and (2) that of medical jurisprudence.

It is with the origin and reproduction of the blood-disks, as with the genesis of a new being; the most intense interest as well as curiosity is excited, and all possible means of research are called into requisition to push, *plus ultra*, the limits of knowledge, and to mark with tangible definiteness the boundaries of legitimate speculation. And it so happens

[1] Dugès, Physiologie. Art. Sang. [2] Flourens, Leçons Orales. [C. J.]

that an integer of the "germ-epithelium" becomes or is a primordial ovum, and that from certain of its derivatives, even in the vascular system itself, the ruddy corpuscles arise, oscillate, and hesitate with uncertain aim, until the *primum movens* gives direction as it acquires power, whereupon they speed away in ceaseless commotion. But the microscope ows the forms of the "primordial blood-colored blood corpuscles,"[1] and ognizes these bodies in all their after career; and yet so differing are gments that they are asserted by Afanasieff to originate in the fowl contemporaneously with the first vessels of the vascular area, or in the vascular layer and area opaca, detaching themselves from the walls of the vascular spaces, or originating, according to the views of His, in the form of groups, from large masses of protoplasm in the walls of the vessels, and at a later period bursting into their lumen.[2]

In mammals it is impossible to adduce other expression than Kölliker's,[3] that at a very early period nucleated colored corpuscles in process of fission are visible in the blood of the embryo.[4] In proportion, however, as the embryo and spleen especially undergo development, these forms are less abundant; and, after a certain time, leucocytes first make their appearance in the blood of the liver. Or that of Schmidt,[5] in a paper "on the origin and development of the colored blood corpuscles in man," which is that "the facts already observed [by him], and being in accord with each other, strongly indicate that the primary birth-place of the colored blood corpuscles in the human embryo is to be sought in the gland-like follicles of the umbilical vesicle." We can, therefore, says the same author, "look upon the blood corpuscle as a *gland cell*," and consider that in early embryonic and in later life the organs in which the processes of generation and formation of the blood corpuscles in man take place, represent nothing else but glands, and that the leucocytes, or rather the nuclei of the leucocytes, are metamorphosed into colored corpuscles.

In January, 1875, the younger Flint,[6] in the first volume of his Physiology, gives a summary of our knowledge, in the present state of which the following seem to be the most rational views with regard to the development and nutrition of the blood corpuscles:—

(1) "At their first appearance in the ovum they are formed by no special organs, for no special organs exist at that time, but appear by genesis in the sanguineous blastema.

(2) "When fully formed they are regularly organized anatomical elements, subject to the same laws of gradual waste and repair as any of the anatomical elements of the tissues.

(3) "They are generated *de novo* in the adult, when diminished in quantity by hemorrhage or otherwise, and, under these circumstances, they are formed in the liquor sanguinis by the same process by which they take their origin in the ovum."

From what has been advanced it appears that in all of the fœtal life of man, regarded as a representative of mammals, four conditions of the blood manifest themselves, to wit: (1) the primordial, colored, flattened corpuscles existing alone at a very early period; (2) the appearance of leucocytes associated with the preceding; (3) the occurrence of circular,

[6] Flint, Physiology, vol. i., Blood, etc.

bi-concave disks mingled with the two other forms; and (4) the withdrawal from the blood-mass of the first formed, the temporary embryonal colored corpuscles, upon which the blood corpuscles, red and white, adopt a relation which is only to be altered by disease or physical violence. And here we are immediately struck with the difference between the transient form as nucleated, and the permanent form as non-nucleated, and we ask ourselves if it can be, as Flint has declared, that the red disks are probably generated by the same process in the embryo and in the adult. If, for a while, we wander from the domain of fact to the regions of fancy, we may find in the works of Leeuwenhoek, that great man largely in advance of his time, a wide generalization deduced from observations made with indifferent lenses, or ill prepared objects. That was about the end of the seventeenth century. In the fourth decade of the eighteenth century (before 1745, the year of his "calling to a new and holy office"), we find that learned visionary, Emanuel Swedenborg, in a tract "written in Latin before his illumination"[1] on the Red Blood, asserting that "the blood contains all organic forms from the primary spiritual, to the ultimate angular, and in this respect is the compendium and complex of all the forms of nature." That "each blood globule contains within it, and carries in its bosom, details more numerous than the eye can ever discover, or the mind conceive." And further he lays down this postulate, that "the red globule admits of division into six lesser and pellucid globules. For six lesser globules have been actually seen in one large blood globule, and, indeed, the mode in which they are united, and the relative position they occupy to each other, have been described and drawn, and wax models representing the whole have been constructed. Moreover, the several lesser globules have been seen in the act of separating from the compound body; and furthermore, experience has shewn that these prior or simpler globules are themselves divisible into still lesser ones, and even into least, when [illogically enough he says] sight can follow them no longer." "All these particulars must be received as true, because the observer, Leeuwenhoek, and the witnesses to his observations, are worthy of credit." And finally, as far as we care to quote this author, Chapter V. opens with the declaration that, besides the lesser pellucid globules which constitute the large globules of the red blood, there are also in the blood certain angular or saline and earthy parts.

Rather more than a century later, in 1846, Dr. Carpenter[2] assures us that the blood corpuscles "are to be regarded as nucleated cells, conformable in general character with the isolated cells which constitute the whole of the simplest plants." And of this there can be, says this eminent author, no reasonable doubt. From this we should infer that they have no power of reproducing themselves; and the recent observations of Dr. Barry and other microscopists seem to confirm the statement made long ago to that effect by Leeuwenhoek. The first change said to take place is the appearance of delicate radiating lines between the nucleus and the periphery, dividing the disk into several segments, usually six in number. The margin is soon observed to be crenated by indentations at corresponding points, and these indentations become deeper until a complete separation takes place, setting free six young cells or disks which seem to have been formed around the border of the nucleus of the parent cell. And therefore should we expect to find, as

[1] Translated by John James Garth Wilkinson.
[2] Principles of Human Physiology, 3d ed., p. 107.

we do meet with, every size intermediate between the small newly generated disk and the full-sized corpuscle. To sum up, therefore, with regard to the appearance in question of the red blood disk being constituted of six parts (Leeuwenhoek[1]) in the usual state, or divisible into seven parts (Barry, Carpenter, and others), six around the assumed nucleus, it may be fairly stated that now-a-days the crenation of the red disk is regarded as the evidence of parting life, or of the earliest post-mortem change.

If we now turn to *form*, we meet with two varieties of colored corpuscles in vertebrated animals, the elliptical and the circular, the former occurring in *fishes* (with the exception of a few Cyclostomata, which have circular disks), all amphibia, and birds, and, among mammals, in the Camel and Auchenia;[2] and the latter characterizing the blood of man and other mammals with the exceptions noted. The red blood disks of all mammals are, according to Rollett, smooth, and give no indication of any difference in the index of refraction of their several parts.[3] In birds, amphibia, and fishes, however, the colored corpuscles do not appear homogeneous, but offer a prominence on either side of the long edge when viewed in profile, which corresponds to a central area somewhat whitish or less deeply tinted when seen on its face. This prominence is absent in Amphiuma.[4] It appears, then, continues Rollett, that we may divide the blood corpuscles of animals into "two classes, the nucleated and the non-nucleated, for the behavior of the central spot is so different from the remaining substance of the corpuscle, but shows so great an agreement with the structure termed the nucleus in other animal cells, that we designate this structure as the nucleus of the blood corpuscle." On this point, as we shall see, Rindfleisch offers a conclusive observation. And we may add our own experience as with Amphiuma, in the staining with magenta and carmine of the large granular nuclei of the colored blood corpuscles in even measure with the nuclei of the giant ciliated epithelial elements of the mouth. Yet before proceeding further it is necessary to recall attention to the fact that nucleated colored corpuscles characterize the embryonal blood of man and other mammals.

Gulliver classifies all blood disks of vertebrates as the Pyrenæmatous and the Apyrenæmatous, which divisions correspond to the oviparous and non-oviparous groups, the corpuscles of all the latter being circular in form and flattened, with the exception of the Camel's and Auchenia's, which are oval but still apyrenæmatous, whereas the colored disks of all oviparous vertebrates are nucleated. But Henle, even in 1843, while claiming the human red blood disks among the nucleated in their early condition, utters words which strongly remind us of the modern Beale in reference to formed and germinal matter. Henle[5] says, "We have yet to show, with regard to the higher vertebrates, as man, that when the coloring matter accumulates in the blood corpuscles, and when their envelope is flattened, their nuclei are dissolved or resorbed, and that consequently the cellule of the blood, arrived at its perfection, is a simple vesicle containing a fluid."

The color, and especially the structure of the disks which we are considering, have greatly occupied the scientific world from the time when Malpighi saw "globulos quasi subluteos in quibus non vidi motum rota-

tionis" until the present time.[1] In man they have been declared to be of a pale-yellow or a reddish-yellow color, quite in opposition to experience elsewhere, which is that no mass of either yellow or reddish-yellow could ever so behave with light as to assume the scarlet hue deep and glowing of the human blood. For this reason we hold the yellow hue in doubt, and because no observer can ever with unaided eye ascertain the true color of a single colored disk. The microscope, in enlarging surface, dims its brightness, and also dilutes or attenuates its color, so that while it is altogether possible by apparatus below the stage of the microscope to compensate for loss of light by the higher powers, no art can restore color to a disk, probably crimson, when its image is amplified ten, a hundred, or a thousand times in diameter. Now what holds good for mammifers, obtains in all probability with the lower orders.[2] In evidence of this statement it will be remembered that the eosenic red of a single corpuscle intensifies if a number of corpuscles lie superposed in the field. In the lower animals the color of the blood, or, what is the same, of the colored corpuscles, varies to some extent, and were our appreciation of the *cachet* of the tints of crimson sufficiently discriminating, we might by recognizing them also identify, probably in this way alone if dimensions failed to aid, the several possessors of the colored disks, as Dugès asserts that the bloods of many creatures have been distinguished from one another by their characteristic aura.

Leaving color we encounter structure, and here most probably begin the real difficulties of our task. The corpuscles of the blood of mammalia, by reason of their size, do not afford facilities for the solution of the first problem as to whether the disks have a limiting capsule. But the larger blood cells of amphibians would seem to offer themselves as easy solvents of the question, especially the frog's ovate bodies and the giant colored and largely nucleated corpuscles of Amphiuma tridactylum. Unfortunately, however, microscopists are not in accord upon several structural points, nor is disagreement confined to them alone. We have already noticed the composite structure attributed to the "red globules" (as they were called by Leeuwenhoek), referred to by Swedenborg, and reproduced by Drs. Barry and Carpenter. But for more than a century, from the time of Malpighi himself, who saw the circulation of the blood and its corpuscles, the idea of an investing membrane and its contents was debated in science, having been suggested most probably by Robert Hooke's description of the cellular structure of plants in 1667. Indeed we find it implied by writers of a later period, as Mandl in 1839,[3] or distinctly expressed, as by Donné,[4] who, in 1844, speaks of the blood disks as being "flattened vesicles containing a more or less fluid substance." And he speaks of the substance of which the vesicle is composed as being of an albuminous nature.

Kölliker[5] entertained the same view, for in 1854 he says "that the blood corpuscle is constituted of a very delicate but nevertheless tolerably firm, and at the same time elastic, colorless cell membrane." "The corpuscle is consequently a vesicle, whence the name blood-cell is to be preferred." More recently Gulliver, in the Proceedings of the Zoological Society, February 25, 1862, speaks of "the embryonic corpuscles as

constituting a first or temporary set." "These cells," continues the distinguished author, "both in structure and size are the true analogues of the red corpuscles of oviparous vertebrates." And again "the corpuscles of the second set are those which replace the first, and, subject to waste and supply, are the red corpuscles of the blood during the greater part of utero-gestation and until death. The corpuscle is not homogeneous, but is composed of a colorless membranous part or basis, separable by water, with a fluid viscid matter in which color resides."

We cannot here enumerate the great authorities who have entertained or who still entertain the view above quoted; it suffices for us to present it as one which still finds favor with many. The contrary opinion, more bold in its enunciation, because at variance with accepted laws, finds its able exponent in Beale, among others. He says in "How to Work with the Microscope," p. 134, that "by drawing a needle across the thin glass under which the red corpuscles are placed, they may be divided into many small globules. This proves that the red blood corpuscles consist of a mass of soft viscid matter, the outer part of which is somewhat hardened." Or again, several red corpuscles may, under certain circumstances, coalesce, and even crystallize without exhibiting indications of any cell wall whatever. Besides the subdivision into small spheres or spheroids, the same author[1] adduces other reasons, as that the mass of the germinal matter in the case of the nucleated blood corpuscle of the frog and other vertebrates, or a portion of it, may pass right through the red viscid material of which the outer part of the corpuscle is composed, without the rupture of any membrane. Now Rollett[2] declares that, "after the cautious addition of water," it frequently happens in the nucleated ellipsoids that the nucleus changes its position in the corpuscle with a jerk, and then lies eccentrically in the corpuscle. Finally Beale remarks, "when water is added to blood corpuscles they swell up just as a piece of jelly would swell up, but they do not burst as is generally stated."

Whichever way we incline, we have fair grounds for our belief, as also excellent authorities and companionship; but we are disposed to favor the modern view, as being more consistent with observations upon fresh blood and blood dried on slides, and as being entirely in accord with what we know elsewhere of protoplasm, especially in the pyrenæmatous colored corpuscles.

Of the leucocytes, what shall we say? What are they? Whence come they? Whither go? And do they appear pathologically under the form of pus? Whatever interest may attach to the *red disks*, the white equally claim our attention; for, in the language of Rindfleisch,[3] "the red blood corpuscles would form one pole, the amœboid colorless cells the other, and, between the two, formation and deformation go continually to and fro."

The colorless morphological constituents of the blood, according to Max Schultze, are of several kinds;[4] "first, round cells, less than the red blood corpuscles, composed of a thin layer of cell substance investing one or two nuclei. With these may be associated other forms, equalling in size the ordinary red blood corpuscles, and like the former possessing

nuclei. Lastly, finely and coarsely granulated amœboid cells are met with, and various intermediate forms between them." "In freshly drawn blood," continues Rollett, "these last appear as more or less rounded or irregularly shaped forms. At a temperature of from 95° to 104°. F., lively movements resembling the creeping motions of an amœba occur." "Such cells," says Frey,[1] "have been seen to pass out (after the manner of an amœba) through the walls of the capillaries (A. Waller, Cohnhein [and Col J. J. Woodward, M.D., in his beautiful photograph of inflammation of the mare's stomach]), towards or through the lining tissue, and to take up into their contractile cell-like bodies small particles, such as molecules of indigo, aniline, cinnabar, and carmine, the finest milk globules, and even extravasated colored blood corpuscles."

These inclusions of red corpuscles by amœboid leucocytes are not to be confounded with "the so-called cells containing blood corpuscles," mentioned by Rindfleisch,[2] who declares that "the opinion only appears to me admissible here that a secondary separation of fibrin has formed about a group of blood corpuscles." And Preyer[3] saw portions of the red blood corpuscles of extravasated blood in amphibia, taken up by white blood corpuscles, and thus explained the nature and mode of occurrence of the bodies that had been previously called blood corpuscle-holding cells. But themselves or their analogues are to be found, according to M. Cornil,[4] in the blood of the spleens of patients who have died in the third week of typhoid fever, in the form of white globules in large numbers, inclosing red globules to the number of five, six, or even more in a single cell. Although, continues the reporter, the existence in the blood of these large cells containing red globules is nothing new, nevertheless Cornil is the first to insist upon their multiplication in typhoid fever.

Besides the remarkable properties of the white corpuscles above mentioned, others equally surprising are most readily brought to the notice of the observer. The migration of these bodies in a drop of the blood of the newt or frog, placed in a moist cell, beyond the limits of a coagulum to the circumvallating zone of serum, has been shown by Rollett[5] to occur, and he points out the advantage of this method of isolating the amœboid cells, and suggests that "the migration of the individual cells renders it clear that the individual movement is the chief if not the exclusive cause of their emigration." In confirmation of the alleged amœboid inclusive movements of the white corpuscles, the famous experiment of Cohnheim was done in the manner to be indicated: "A small quantity of finely granulated coloring matter, suspended in water, is to be injected by a Pravaz's syringe on several consecutive days into one of the large lymph spaces which lie under the skin of the frog. On examining a drop of blood, a considerable number of the colorless cells will now be seen to be stuffed with the granules."[6]

Four chief matters of interest in connection with the white corpuscles deserve at least passing notice in this place:—

(1) Their origin, which elicited from Rollett[7] the following summary: "Whether the colorless corpuscles always undergo multiplication within

[1] The Microscope, etc., Dr. Heinrich Frey; New York, 1872, p. 102.

the blood itself, and by what mode of cell genesis they multiply, are still open questions. It is certain," says that author, "that a large number of white corpuscles are added to the blood, not only during the period of development and growth of the animal organism, but also throughout life by the agency of the lymph current, the corpuscles of this current originating in localized germ-producing organs situated external to the blood (lymphatic glands)." Our own observation of the blood of a young seventeen inch long Amphiuma tridactylum, goes to show that the leucocytes had greatly multiplied in number after the head had become much inflamed in consequence of repeated attempts of a larger Amphiuma to swallow that which was the subject of experiment. Again, the pathological process of leukæmia,[1] so called, seems to be associated with an increase in volume of the spleen, and often at the same time of the lymphatic glands, although but seldom caused by the enlargement of the latter organs alone.

(2) Their transformation into red or colored corpuscles, for which in the frog we have the authority of Recklinghausen, Sclarewsky, and Golubew, but which if it do occur in the human subject, happens very slowly in convalescent leucocythæmic patients. The intermediate forms met with in the blood of the frog were known, but not correctly referred, by the earlier observers, as Wharton Jones and Hensen.[2] Besides we have also the authority of Bizzozero and Neumann[3] for the statement that the transformation of the lymphoid cells may be seen in the red bone-marrow of mammalian animals; and this bone-marrow itself, is, according to some authors, as Frey, one source of origin of the colorless cells of the blood.

(3) Their relative proportion to the red corpuscles cannot be regarded as fixed, for the averages of the best observers, as Welcker and Moleschott, differ sensibly. Thus, Welcker states his average as one white corpuscle to three hundred and thirty-five (335) red, while Moleschott finds one in three hundred and fifty-seven (357). The proportion also varies with age, their number being greater in the young than in adults, and, according to Hirt, they increase during full digestion, but diminish in fasting. And lastly, Hirt[4] "found the number of white corpuscles seeming greatly to differ in various parts of the vascular system; thus in the splenic vein they are as one to sixty (60) red; in the splenic artery as one to two thousand two hundred and sixty (2260); in the hepatic vein one to one hundred and seventy (170); and in the portal vein as one to seven hundred and forty (740).

(4) The migration of the lymphoid cells into the space of the connective tissue, and their relation to the pus cells. In this connection the great name of Cohnheim immediately rises before us. His observations. confirming the older views of A. Waller, possess, says Frey, "an extraordinary range, and have rapidly called forth an entire literature." In connection, however, with this subject, interest may be awakened by reference to the conviction of Mandl, expressed in 1839, that "we[5] demonstrate the perfect identity of globules of pus and of the fibrinous globules of the blood . . . as we understand it." Henle[6] soon after declared that he had "shown that the nuclei of the lymph corpuscles go through the same metamorphoses as those of pus; they differ by their volume

only." And in a note added by Prof. Stricker to the American edition of his Histology, 1872, page 47, that eminent scientist assures us that his "later investigations have shown that the process of division of pus cells can be directly observed under the microscope." But most curious are the general conclusions arrived at by Mandl in his Memoir, read before the Société Médicale d'Émulation, June 3, and found in the Gazette Médicale de Paris, July, 1840. They are as follows:[1] "1. The fibrinous globules of the blood, the globules of mucus, and those of pus, are identical. 2. All the globules are the product of the coagulation of the fibrin in the serum, which has transuded through the walls of the bloodvessels. 3. The liquid in which the globules swim constitutes the difference between pus and mucus. 4. If the fibrinous globules remain fixed to the surface of the membrane where they are secreted, they become the nuclei of epidermoid cells, which constitute the elements of the epidermis. 5. If, on the contrary, the fibrinous globules remain free on the surface of the membrane, they are expelled by the organism, and form an element of pus and mucus. 6. These two elements are simply filtered blood; that is to say, they contain the elements of the blood, except the globules, the serum at the same time undergoing chemical alteration."

In opposition, in Virchow's Archiv, Bd. lxii. S. 47 (1876), we find that Professor J. Arnold discovers "the white corpuscles themselves in the act of escaping in an inflamed tissue, through the cement substance, that is the stigmata, and that gelatine and vermilion also pass through the cell wall at the position of the stigmata and cement substance."[2] How well Mandl saw, but failed to interpret, may be understood by a comparison of his conclusions, in 1840, with the beautiful researches of Waller, Cohnheim, Woodward, and J. Arnold, in later years.

As soon as the corpuscles of the blood were an assured acquisition to science, they very naturally attracted and received great attention for themselves as wonderful objects on account of the rôles which they were supposed to play in physiology, and because of the very great importance which their possibly positive recognition in the several classes or genera of animals would necessarily assume in medico-legal investigations. The interest in these elements has continued unabated until the present hour, and all the resources of art have been put in requisition to insure not only their detection under all and difficult circumstances, but also to make certain their specific identification. To this end many devices have been put in practice, such as bettering the modes of presenting the corpuscle in every state for investigation; the use of high powers, and improvement in the quality of the objectives employed in their study; their exact mensuration, relative and positive; their enumeration; the establishment of the normal proportion existing between the colored corpuscles and the leucocytes; and, finally, an appeal to the spectroscope, which might discover in the minutest trace of cruorin the ghost of even one departed red disk which had yielded up its form.

With regard to the first of these efforts, the best condition under which these little bodies may be thoroughly investigated, we have nothing to urge in behalf of the various preservative fluids which have had fortune with microscopists, being satisfied that, as far as our own experience extends, the question is not as to how excellent a substitute may be pro-

[1] Microscopical Journal, 1841, p. 80. [2] Monthly Microscopical Journal, June, 1876.

vided for the liquor sanguinis, but rather how greatly superior is the liquor sanguinis itself. Of course, this view involves the necessity for a limited range of observation by each of the scattered students of comparative hæmatology, for it is not given to each and several of these to push inquiry with all the special bloods in their living or immediately recent state. Amphiuma, proteus, and the musk deer, are not only strictly local, but are very widely separated geographically; the standard bloods, however, are almost everywhere accessible, for the frog, the horse, the cat, and the dog, fishes and newts, are almost *passim;* and thanks to itinerant menageries and fixed zoological collections, many strange animals are assembled in unfamiliar districts. Besides, we can have, or ought to have, human blood at our own finger ends.

For use as artificial standards, the corpuscles, mounted dry on the under surface of the thinnest cover, are decidedly of the greatest service, for as all mammiferous red disks, and perhaps a few of the other smaller forms, confessedly shrink but little, and as in medico-legal investigations the expert has usually to deal with dried hemorrhagic stains or clots, like is directly compared with like, as could also easily be done if exceptionally immediate blood were obtainable as food for the microscope or spectroscope. But let it be well understood that we greatly prefer the recent, the living blood, if possible, on every account. Form is unaltered; all physical qualities are unchanged; characteristic behavior at the normal temperature, and in presence of such reagents as magenta, acetic acid, water, or an alkali, is conspicuous; and heat, or life, or light, or other modes of motion, start up in microcosmic play.

With regard to the methods of perfecting objectives, we propose to be silent, leaving the problems which these create to our own Tolles and Spencer, to Powell and Lealand, and the Becks, to Wales and Ross, to Zeiss and Seibert, to Scheik and Plössel, and last, but not least, to Woodward, and Wenham, and Keith. But we accept the superb work of the great artist-scientists of the day, and we rejoice in the splendor of their instruments.

More germane to our subject is an expression of opinion as to the degree of amplification requisite for exhaustive and conclusive study of the blood; and at once the microscopist is struck with the necessity for the employment of high powers for all research excepting only what might be called a general view of the field. For enumeration of the corpuscles, a medium power suffices; for acquiring a collective idea of blood, either in the vessels, or freshly drawn, placed on a slide, and subjected to changes of temperature and the action of reagents, moderate amplification offers the best hope; but for higher views, higher objectives must be put to use, and an immersion[1] $\frac{1}{16}$, $\frac{1}{30}$, $\frac{1}{50}$, or even $\frac{1}{75}$ inch objective, of the best maker, and of large angle, in the hands of a really good manipulator, will afford a demonstration of all that is at present attainable. If size alone be in question, it is unscientific to hope to distinguish, under low powers, human red corpuscles with an average diameter of $\frac{1}{3230}$ of an inch from those of the dog with an average measurement of $\frac{1}{3576}$ of an inch;[2] and it is worse than unscientific to obtain large images by forcing low objectives with short eye-pieces. We hold, therefore, that, with the results of mensuration of the blood-corpuscles, all the conditions attending the measurements must be given, if their authors

[1] Woodward.

[2] Prof. Theo. G. Wormley, letter to author, May 16, 1876; New Measurements.

expect to win and maintain the confidence of the world of science. Thus Prof. Theo. G. Wormley regards the condition of his material as attached to the under side of a thin cover; the thickness of that cover; the temperature of the slide, by averaging measurements made at all seasons of the year; the position of the collar of adjustment of the objective; and the identical disposition of the light in all observations; and he employs a $\frac{1}{32}$ inch objective. Besides, he has repeatedly tested the assumed value of each of the divisions of his micrometer, and confined himself to the employment of that or those only of which he has assured himself as being absolutely true to the standard.

Before proceeding further with mammalian blood, let us not lose sight of what is most probably quite as important as size, namely, the *cachet*, or stamp of individuality possessed by each of the kinds of blood disks, the determination of which is or will be a matter of necessity in microscopy simple or applied. In support of this view, we would ask a serious contemplation of two similar bloods on the same slide, of a feline, and of an herbivore. Difference in diameter under a tenth objective may not be a striking feature of the contrast, but a sentiment of something beyond, for which we may not as yet account to ourselves, immediately but stealthily takes possession of our senses.

It was with the intention of arraying in the opposition of contrast human blood and the dog's, and human blood and the cat's, that that well-known scientist, Dr. Joseph G. Richardson, flowed drops of blood from different animals so nearly in contact on a glass slide, that portions of the two drops appeared in the same field, and could be photographed together.[1] Dr. C. Leo Mees, assistant to Prof. Wormley, in Columbus, Ohio, modified this plan, spreading the bloods by the present writer's method, a half field upon a slide, and another half field upon a cover, which is then turned down and placed directly upon the slide. The method consists in catching a small drop of blood with the true edge of a well-ground slide, and gently drawing it, that slide being inclined, over the face of another slide or cover. Dr. Mees obtains half fields by scraping. "In this manner," says Prof. Wormley, "we obtain the bloods virtually upon the same plane for powers under the $\frac{1}{5}$ inch." But after inspection, we fear much for the assumption "virtually upon the same plane," even for a large angle, $\frac{1}{5}$ inch; nor are we prepared to admit the availability of such slides for Prof. Wormley's very fine $\frac{1}{32}$ inch objective. And besides we are persuaded that the cachets of the two bloods, if they ever can be recognized as distinctive, will hardly bear comparison when the disks of one blood present their attached and flat surfaces towards the observer, and the other disks their free, and, in the instance of circular mammalian disks, their excessively concave sides.

As measurement of the blood-corpuscles, colored and pallid, is nowadays scrutinized by the keen eyes of microscopical science and of the law, we propose to offer in this paper some of the best modern and most careful observations. But as a preparation for accepting the results of so much patience and labor, and great skill, we beg to present a list of measurements of the human blood in Hodgkin's and Lister's Microscopical Observations, contained in the Philosophical Magazine, vol. xi. p. 133, as given in the Microscopical Journal for 1841. It is as follows:—

[1] American Naturalist, May, 1876.

Hodgkin	$\frac{1}{3000}$	of an inch.	
Jurine	$\frac{1}{5240}$	"	
Jurine	$\frac{1}{1940}$	"	(Second measurement.)
Bauer	$\frac{1}{1700}$	"	
Wollaston	$\frac{1}{5000}$	"	
Young	$\frac{1}{6060}$	"	
Kater	$\frac{1}{4000}$	"	
Ditte	$\frac{1}{6000}$	"	
Prevost and Dumas	$\frac{1}{4076}$	"	
Nasse[1]	$\frac{1}{3703}$	"	

A difference so remarkable as that between the $\frac{1}{1700}$ and the $\frac{1}{6060}$ of an inch, inspires little confidence in the means and the method, and such series of observations must be now regarded as curiosities of microscopy.

Passing over the great hiatus separating the year 1840 from the time in which we live, we would deal directly with four papers relating to comparative measurements of the colored blood disks of vertebrates, two of which are from the pen of Joseph G. Richardson, M.D., of Philadelphia, one by Col. J. J. Woodward, M.D., U. S. A., and the last and most recent, by Prof. George Gulliver, F.R.S. In the first of these[2] "On the value of high powers in the Diagnosis of Blood Stains," an article of much merit, the author "endeavored to work out a conclusive answer to the question," "whether practically we can or cannot discriminate the stains of human blood from those made by the blood of oxen and sheep." "In conclusion," he says, "I submit that the results of my experiments above narrated, *prove* that since the red blood-globules of the pig ($\frac{1}{4230}$ of an inch), the ox ($\frac{1}{4267}''$), the red deer ($\frac{1}{4324}''$), the cat ($\frac{1}{4404}''$), the horse ($\frac{1}{4600}''$), the sheep ($\frac{1}{5300}''$), and the goat ($\frac{1}{6366}''$), are all so much smaller than even the ordinary medium size of the human red disk, as measured in my investigations, we are now able, by the aid of high powers of the microscope and under favorable circumstances, to positively distinguish stains produced by human blood from those caused by the blood of any of the animals just enumerated; and this after the lapse of five years from the date of their primary production." "We may add to these, the average measurements, those of recent blood disks procured from a blood spot moistened with a one per cent. solution of common salt, and stained with a drop of [red ?] aniline solution. Thus the mean of ten corpuscles so treated was expressed by the fraction $\frac{1}{3425}$ of an inch. the minimum being $\frac{1}{3572}$ of an inch, and the maximum $\frac{1}{3125}$ of an inch."[3] Notwithstanding the expression of belief[4] that the red corpuscles "rarely contract," the author gives the maximum $\frac{1}{3231}$ of an inch, minimum $\frac{1}{3500}$ of an inch, and mean $\frac{1}{3355}$, of twenty recent red corpuscles of a white male aged thirty. But again, and on the opposite side, "the measurement of twenty corpuscles from part of the same specimen dried in a thin film upon a slide gave a maximum of $\frac{1}{2800}$, a minimum of $\frac{1}{3621}$, and a mean diameter of $\frac{1}{3182}$ of an inch."[5] And in the Oswego Greenfield trial, in June, 1876, Dr. Richardson testified that "drying diminishes all kinds of corpuscles."

The second paper, by Col. J. J. Woodward, M.D., U. S. A., almost exhaustive in reference, and most ably presenting the author's research and observations, appeared in the Monthly Microscopic Journal of February, 1875, five months after the valuable article just noted, and was suggested by it as the first line distinctly assures us. The title is as follows: "On

[1] Valentin's Repertorium, 1840.
[2] Monthly Microscopical Journal, September I, 1874.
[3] Loc. cit., p. 140. [4] Loc. cit., p. 137. [5] Loc. cit., p. 135.

the similarity between the red blood corpuscles of man and those of certain other mammals, especially the dog, considered in connection with the diagnosis of blood stains in criminal cases." The general tenor of this paper is a dissent from the conclusions reached by Dr. Richardson. Among the most striking points of stress of Col. Woodward, is the statement: "For myself, after repeated measurements of the blood of the dog and of human blood, I can only say that I find no constant difference between them, whether the fresh blood or thin layers dried on glass be selected for measurement. The mean of fifty corpuscles, taken at hazard, is seldom twice the same, and sometimes that of human blood and sometimes that of the dog's blood is a trifle the larger." In the same connection, a little further on, the author gives two tabulated records of measurements of red blood corpuscles, which very remarkably substantiate the afore-mentioned doctrine, the one being measurements of red corpuscles of human blood and the other of the same elements of the dog. In both cases the blood was obtained from five individuals; fifty corpuscles formed the basis of each observation; of the thirteen specimens of human blood measured, four were moist; of the nine of dog's blood, five were moist, and, singularly enough, "in each of the measurements" of the two bloods "the great majority of the corpuscles ranged from 12 to 17 divisions of the eye-piece micrometer: that is, from .00024 to .00034 [or $\frac{1}{4166}$ to $\frac{1}{2941}$] of an inch."

Before quitting this important field, Col. Woodward reminds the reader that "the variations between the mean diameters assigned to human blood by different observers are quite as great as the variations recorded by any of them between the blood of man and of the dog, or even greater." Although there is admitted to be "no constant difference" between the wet and the dry corpuscles, when fresh and used moist, or quickly dried on thin glass, it is denied that a differential diagnosis can be possible in the case of "blood dried *en masse*, when sprinkled on weapons, clothing, wood, etc., for no one will pretend that it can be any easier to make the diagnosis of such stains than it is in the case of moist blood or of thin films dried on glass."

In the same Journal, for May, 1875, Dr. Richardson replies to the strictures of Col. Woodward, but states explicitly his "full corroboration" of Col. Woodward's assertions, and declares that "there is at present (1875) no method known to science for discriminating, microscopically or otherwise, the dried blood of a human being from that of a dog, monkey, rabbit, musk-rat, elephant, lion, whale, seal, or in fact any animal whose corpuscles measure more than $\frac{1}{4000}$ of an inch in diameter." With this admission we would fain conclude our notice of the article, but fairness demands that the criticism of Col. Woodward, which we have reproduced, should be followed with an explanatory statement from Dr. Richardson, who says: "I wish to insist most emphatically that all my statements in regard to the diagnosis of blood stains are applicable to *stains* only, and not to *masses* of dried blood clot." And we here would call attention to the fact that in the case of State *v.* Lodicia and Albert Friedenburg, for the murder of Orlo Davis, tried in Utica, in November, 1875, Dr. Richardson testified[1] that he had examined certain spots on an axe helve and "had come to the conclusion that the corpuscles, or red blood disks, or globules, were those belonging to human blood." And again in the Greenfield trial, held in Oswego, in June, 1876, Dr. Richardson, after

[1] Utica Morning Herald, Friday, November 19, 1875.

examining dark spots on some chips belonging to the rail of a bedstead, testified as follows: "If the question is narrowed down to whether this is human blood or sheep's blood, I can say positively that this is man's blood. Because the corpuscles are such as could never circulate in the veins of a sheep."[1]

In opposition to such testimony and teaching, we find in Dalton's Treatise on Human Physiology, sixth edition, 1875, an expression of views which will meet with favor with the majority of advanced observers and thinkers. He says: "If a blood stain which in a watery solution gives the common spectrum of hæmoglobuline, be found to contain oval nucleated globules, this would show it to be the blood of a bird, reptile, or fish; and the oval form alone would show that it was not human blood. The question, therefore, whether a particular specimen be composed of human blood may often be decided with certainty *in the negative* by microscopic examination. But if the specimen contain circular globules without nuclei, it will be impossible to say positively in any instance that they belong to human blood, and not to that of some animal, such as the ape or dog, whose red globules nearly approach the human in size. In most of the domesticated quadrupeds the globules are smaller than in human blood, but in both the sloth and the elephant they are larger. If it were only required to decide whether a given specimen of fresh blood belonged to man or to the musk deer, for example, or even the goat, no doubt the difference in size of the globules would be sufficient to determine the question. But within nearer limits of resemblance it would be doubtful, because the size of the red globules varies to some extent in each kind of blood; and, in order to be certain that a particular specimen were human blood, it would be necessary to show that the smallest of its globules were larger than the largest of those belonging to the animal in question, or *vice versâ*. The limits of this variation have been tolerably well defined for human blood, but not sufficiently for many of the lower animals to make an absolute distinction possible. In the examination of stains or blood spots the difficulty is increased by the fact that the drying and subsequent moistening of the globules introduces another element of uncertainty as to their original size."

The last paper we propose to notice, and the most remarkable of its kind which science possesses, is entitled Observations on the Sizes and Shapes of the Red Corpuscles of the Blood of Vertebrates, with drawings of them to a uniform scale, and an extended and revised table of measurements, by George Gulliver, F.R.S.; and appeared in the Proceedings of the Zoological Society of London, for June 15, 1875. The "present purpose" of this extremely sagacious and very laborious production "is to give simply the averages, with brief explanatory comments, of numberless measurements all made by me," says Prof. Gulliver, "in the hope that they may be useful towards further researches of the same kind." "The measurements now recorded show the labors of many years," and consist of "many additions and revisions by new observations made since publication, upwards of a quarter of a century ago," of Prof. Gulliver's tables of measurements, which originally appeared in the Proceedings of the Zoological Society, in 1845.

Simple as is the announcement, the variety and originality of the observations, inferences, comparisons, and deductions would be very surprising were it not for a knowledge of the author, and of the fact that they are the

[1] Oswego Daily Times, Saturday evening, June 10, 1876.

developed germs of more than thirty years of toil. It is foreign to our purpose to follow this observer in all the paths that he has trod, but we confine ourselves to the matter of measurements, and in this circle alone we find abundant food for careful thought. Although the table of averages "has been deduced from innumerable and generally correct observations," the red corpuscles are found usually to differ among themselves in every field of vision, commonly to the extent of one-third larger or smaller than the mean. And when we reflect upon "the real variations in size produced in the bird alternating between rest and excitement; the probable diversities in some vertebrates at different times and seasons; the possible ones influenced by climate, rest, and violent exertion, periodical rise of temperature—as in python, sex, the system—whether arterial or venous, the ever-varying state of the liquor sanguinis,[1] pathological or septic changes," it need not surprise us that the author advances the proposition "or fact that in a single healthy species the corpuscles are so prone to minute variations of size that no two observers, nor even one observer, can be certain of obtaining precisely the same average measurements." Nevertheless "the relative value of the measurements, though probably not unexceptionable, may be entitled to more confidence as fair approximations to the truth."

The applications of what has preceded are extremely numerous, and if it had been possible to extend the scope of this paper their number would have been measurably increased. But we will here refer to but two, as perhaps the chief among them, the physiological and the medico-legal. In the former connection we encounter bodies doubtless of the same significance and function, but which differ strikingly in size, *cachet*, and form, and what is more remarkable the almost perfect correspondence established between a majority of[2] mammalian vertebrate and apyrenæmatous red blood corpuscles, having a discoid-biconcave form, and between oviparous vertebrate and oval pyrenæmatous blood disks. But while the oval blood disks of the exceptional camel conform in smallness of size to the circular corpuscles of other mammalia, they are non-conformable to the oval pyrenæmatous type of oviparous vertebrates. In general, with regard to size in apyrenæmata, we are called upon to admit as "a rule that the largest corpuscles occur in the large species, and the smallest corpuscles in the small species of a single order or family. It extends to the whole class of birds, but neither to reptiles, batrachians, nor fishes, except in some partial instances which seem to be rather indeterminate or accidental than regular."

After form and size, we naturally encounter number, which conspicuously has importance in relation to physiological or pathological action. If with Schmidt[3] we assume the blood mass in a human subject to weigh 10 kilogrammes (26 pounds 9 ounces, troy), then the sum of the blood cells would amount to 56 billions 570,000 millions. But this vast figure gives us no advantageous information, and its consequence fades out before the more practical efforts of Vierordt (1852) and Welcker (1853), the former of whom counted all the red disks in a known cubic measure of blood, by successive instalments poured and dried upon a slide, and reducing his calculation to one millimetre, obtained at first 5,171,400, and at a later period 5,055,000. Welcker, both by counting the red corpuscles in blood diluted with albumen, with the aid of a crossbar

[1] Also Kölliker, op. cit., p. 605.
[2] Gulliver, loc. cit., p. 482.
[3] Kölliker, op. cit., p. 569.

ocular micrometer, and by comparing diluted blood with an established color scale, fixed his estimate at 4,600,000 corpuscles in a cubic millimetre for a healthful person, 3,800,000 in an hysterical person, and 2,400,000 in a patient far advanced in consumption.[1]

We next refer to the advance made by Potain[2] in estimating the number of red corpuscles contained in a cubic millimetre, by counting a small portion of diluted blood, and to the labors of Mélassez[3] in blood counting. The hæmatimètre of Hayem and Nachet, recently described by Mélassez,[4] in the hands of Drs. E. L Keyes and L. A. Stimson, gave as an average of 33 counts the number of red corpuscles in one cubic millimetre as 4,990,550, a table derived from exceptionally good sources. "The above estimate," says Dr. Keyes, "of nearly 5,000,000 blood corpuscles for the cubic millimetre, I believe to be a high average for Americans in the neighborhood of New York, during the summer and autumn."

"To compare the above results with those obtained by other investigators, we find that Hayem[5] places the mean at about 5,000,000 more or less, for the blood of the finger of the healthy adult male; Vierordt[6] established as a mean for his own blood something over 5,000,000; Welcker[7] estimated it at 4,600,000; Cramer at 4,726,000. Mélassez gives the lowest average, placing the number at something less than 4,500,000, but he is not very definite upon the subject of healthy average, being more interested in his writings in a description of the instrument and in considerations of diseased blood." "In the most extreme cases of anæmia (excepting only two cases), Hayem never counted less than 3,000,000." In this respect my own experience, concludes Dr. Keyes, "has been similar to his."

In this last connection it deserves to be noted that Dr. Ordenstein, of Paris, suggests the possibility of a connection between leukæmia and hereditary syphilis, and in a case of his own exhibited Van Swieten's solution of bichloride of mercury for several months with surprising benefit.[8] And finally we feel constrained to mention the conclusions arrived at by Liègeois and Wilbouchewitch, as quoted by Keyes, and those of Dr. Keyes himself: (1) that syphilis diminishes the number of red corpuscles below the healthful standard; (2) that mercury in small doses, continued for a short or for a long period in syphilis, alone or with iodide of potassium, increases the number of red corpuscles in the blood, and maintains a high standard of the same; and (3) that mercury decreases the number of red cells when given in excess, especially in hospitals.[9]

Not less interesting, and certainly not less important, than the physiological, is the medico-legal application of what the microscope may teach. The law calls upon the expert to be thoroughly *au fait* in all that modern science has established with regard to the blood in its living and in its dead state, in its youth and adult periods, in its pathology, in its different and indifferent conditions of preservation, in dryness and in moisture, in heat and in cold; and the character, size, form, and number of the corpuscular elements in all attainable classes, orders, species, and families of the zoological series. Nor will his attainments be re-

[9] Keyes, loc. cit.

garded as determinative, unless he be also master of micro-chemistry and familiar with absorption bands, and the expression of their wave length,[1] awakened in ghostly shapes in the spectroscope made an ally to the microscope. In short, accusing justice, and defensive crime or innocence, claim not only an absolute recognition of blood, as distinguished from all other matters or elements whatsoever, but the specific determination of the kind of blood, as well as a positive acquaintance with all the disturbing agencies of time, heat, dryness, and moisture, as affecting the *cruor* offered in condemnation or exculpation.

That microscopical science is so assured in her varied knowledge, even if its application be restricted within very narrow limits, cannot be asserted. From what has preceded it must appear that even for human red blood disks there is no fixed and established standard. The observations of Gulliver upon the variations in size of the red corpuscles in birds, under the different circumstances of excitement and repose, and the positive statement of Col. Woodward that "the blood disks of different persons, and even of the same persons at different times, vary more in size than the ordinary difference between human and dog's blood," are germane to this issue. But we would consider our task as glaringly incomplete if we failed to give becoming prominence to the averages of the most perfectly conducted work of our distinguished friend, Prof. Theo. G. Wormley, M.D., of Columbus, Ohio, and to state the expression of his variance with Col. Woodward's record, that "this is certainly contrary to *all* our own experience."[2] With Dr. Wormley's permission we offer a few of his measurements, which were furnished in the course of a recent correspondence:—

Human blood, average of all averages, including over 2000 measurements		$\frac{1}{3230}$	inch.
Dog,	average of averages	$\frac{1}{3576}$	"
Cat,	" "	$\frac{1}{4372}$	"
Rat,	" "	$\frac{1}{3652}$	"
Horse,	" "	$\frac{1}{4202}$	"
Jack,	" "	$\frac{1}{3507}$	"
Mule,	" "	$\frac{1}{3760}$	"
Ox,	" "	$\frac{1}{4119}$	"
Opossum,	" "	$\frac{1}{3142}$	"
Muskrat,	" "	$\frac{1}{3282}$	"

To these measurements the following is added as a note: "You are aware, I believe, that in getting our standard for micrometry every possible care was taken to have it correct. The ordinary scales are subject to considerable variation." In acknowledging the favor of the above, we beg to add that we have seen the whole record of the admirable averages of Prof. Wormley, the work of many years, which evidences the industry, the patience, the intelligence, and the scrupulous fidelity of the author.

It had been our purpose here to close this essay, but we pause to notice a paper by Col. Woodward, read at the Centennial meeting of the American Medical Association, which has for its title "The Application of Photography to Micrometry, with special reference to the Micrometry of Blood in Criminal Cases." By the plan proposed, which may be destined to supersede all others, and to abate the value of all former more laborious and less exact procedures, "the blood is placed on a glass stage

[1] Sorby, Monthly Microscopical Journal, May 1, 1875.
[2] Letter to Author, March 28, 1876.

micrometer, and photographed with any convenient power;" and in the elegant photographs offered in illustration "both blood and micrometer appear sharply defined. The measurements are then made on the negative." "For the purpose of soaking out blood stains" the able author prefers to "use a strong solution of caustic potash, as described by Virchow in 1857." The development of this mode of fixing the averages is insisted upon by the distinguished microscopist, who now regards the eye-piece micrometer as a "snare and a delusion," and claims that the negative on glass possesses an exactness which may be expressed in millionths of an inch, and may be tested at leisure by any number of persons. And another point of interest attaches to these light pictures, *i. e.*, the equal delineation, *under high powers*, of all corpuscles, whether large or small, of normal shape or deformed.

Remotely related to the subject are the "micro-photographs of the blood in disease," recently issued by Dr. E. Cutter, of Cambridge, and Dr. G. B. Harriman, of Boston.

In conclusion we beg to remark that the copious literature of this extensive subject, the Microscopy of the Blood, is nowhere complete in this country outside of its Capital; and that, in spite of the distinguished courtesy of the eminent scientist in charge of the Army Medical Museum, this treasury of knowledge cannot always be made available by the busy professional men who reside at a distance.

Discussion on Dr. Johnston's Paper.

After the reading of the preceding paper, Dr. J. G. Richardson, of Philadelphia, said:—I should like to offer an explanation in reference to my testimony at the trial in Herkimer County, New York. I did not state absolutely that the corpuscles were those of human blood, but that they *corresponded* to those of human blood. Microscopy has long been employed as an aid to the administration of justice; and serves easily, for example, to distinguish human blood from that of a fish, because the corpuscles in the former are round, while in the blood of the fish they are oval. At first the legal authorities demanded no more than this, but when the facilities for microscopic examination became more complete, we began to draw a still sharper line of distinction—that is, one between human blood and that of the musk-deer or goat. Now, with improved immersion lenses, we are, I contend, able to distinguish between the blood of a human being and that of an ox, horse, or other animal having corpuscles of similar size; but when circumstances do not thus narrow down the demands of justice in a trial, I would never attempt to discriminate the kind of blood with certainty. Our power to aid justice in this matter is due to the fact that when a man is arrested with blood-stains on him, and tries to explain how they got there, he generally alleges that he has been in a position to be stained by the blood of some animal; and then, by microscopic examination, we can distinguish between human blood and that of the ox, pig, or sheep, to which the suspicious stains are usually attributed.

Dr. Johnston said:—That would not be a positive recognition of human blood-disks, which is what the courts desire; for the blood might be that of a dog or guinea-pig, and not of a human being.

Dr. Henry D. Didama, of Syracuse, N. Y., said:—I know of a case in which the question presented was, whether the blood was that of an ox or human being; and though, in such a case, an expert might not be able to say that the blood was human, yet he could prove that the statement made by the criminal

was untrue. I wish to ask Dr. Johnston whether, if he should find a blood-disk $\frac{1}{3200}$ of an inch in diameter, he would be willing to swear that it was not the blood of an ox or pig? because, as I understand the matter, the blood-globules of the ox and pig never reach that size.

Dr. JOHNSTON said:—Where the variations were not exceedingly great, I would be unwilling to give an opinion.

Dr. RICHARDSON said:—I understand Prof. Johnston to say that, on examining some unlabelled slides of man's, dog's, and guinea-pig's blood, offered him by Dr. J. J. Woodward, he found himself unable to discriminate between them. This is what I should expect; but I would like to ask Prof. Johnston whether, if a person of unproved veracity should bring him a specimen of blood, covering the name, and telling him that it was from a sheep, and he should find, on measurement, that the corpuscles averaged $\frac{1}{3200}$ of an inch in diameter, he would not feel justified in contradicting the statement?

Dr. DIDAMA said:—Would not Prof. Johnston, if he found blood-disks of $\frac{1}{3200}$ of an inch, be certain that they could not have circulated in the capillaries of a sheep?

Dr. JOHNSTON said:—It is a very difficult question to answer, as both vessels and corpuscles are extremely elastic, and capillaries constantly allow corpuscles to pass through them, which are larger in diameter than the capillaries themselves.

Dr. JAMES TYSON, of Philadelphia, said:—It seems to me that this is an ambiguous mode of putting the question, because, as Dr. Johnston says, even if we could assert that a particular blood was not that of a sheep, we could not say that the corpuscles could not have circulated in the capillaries of a sheep, on account of the property of elasticity correctly attributed by Dr. Johnston to both corpuscles and capillaries, to say nothing of the varying size of the latter. But the fact is that the peculiar organization of the human mind has something to do with the drawing of conclusions. Some persons would feel at liberty to draw the same conclusions from the premises named by Drs. Didama and Richardson as they, while others would not. I, for example, would be willing to say that such blood was *more likely* to be that of an ox or sheep than that of a man, while I might not be willing to say absolutely "this is the blood of an ox or sheep," and not that of a man.

Dr. S. E. CHAILLÉ, of New Orleans, said:—I desire to ask two questions: I think we all agree with Prof. Johnston that human blood corpuscles cannot be positively distinguished from all others; but frequently, in court, some witnesses assert that a particular stain is human blood, while others say, no, it is the blood of an ox. The Court asks the microscopist, "Can you decide whether this is human blood or that of an ox—or, let us say, of a sheep?" Is it Prof. Johnston's opinion that such a decision could be made, and would he, under such restricted circumstances, feel justified in saying whether the blood was that of a sheep or of a man?

Dr. JOHNSTON said:—I could answer negatively, that the blood was not human.

Dr. CHAILLÉ said:—My second question is this: I have been told that certain specimens of blood have been offered to Dr. Richardson, and that he has been able to discriminate between them. I would ask of Dr. Richardson if such is the fact?

Dr. RICHARDSON said:—Such was the case, not in one series of specimens only, but in two.[1] The number of samples in each series was three; one being the blood of an ox, one that of a sheep, and the other human blood. I was able to distinguish between them by microscopical examination alone.

Dr. JOHNSTON said:—There is more than the mere diameter of the corpuscles to be considered; we must consider the *cachet*, or the stamp of individuality of the blood.

[1] See American Journal of the Medical Sciences, July, 1874; also, London Monthly Microscopical Journal, Sept. 1874.

Dr. L. S. Joynes, of Richmond, Va., said:—I would like to ask Dr. Richardson as to the relative ease of distinguishing between different bloods when dry and wet. Can we restore dried corpuscles so certainly as to distinguish whether they are human or otherwise? It is difficult to know how far blood corpuscles on the clothing are altered from their original condition.

Dr. Richardson said:—My experience has been that in dry blood-stains there is a shrinkage of from five to ten per cent. That is, that the fresh blood corpuscles of man average $\frac{1}{3200}$ of an inch, while in stains they measure from $\frac{1}{3400}$ to $\frac{1}{3700}$. The blood corpuscle of an ox, which averages $\frac{1}{4267}$ of an inch, when fresh, would measure $\frac{1}{4600}$ or $\frac{1}{4700}$ after re-moistening.

Upon the conclusion of the discussion, Dr. Richardson said:—As strong evidence of the presence of a true cell-wall in red blood corpuscles, upon the existence of which the value of my method for the diagnosis of blood-stains largely depends, I invite the members of the Section to inspect, beneath a Holmes's class microscope, a red disk of the Amphiuma tridactylum, in which the imperfectly crystallized cell-contents occupy the upper end, while the oval granular nucleus fills the inferior extremity, leaving the membranous capsule relaxed and wrinkled longitudinally, hanging like part of a half-flaccid balloon between them. (Fig. 1.) I also show, as corroborative testimony, a slide

Fig. 1 (× 400).

Fig. 2 (× 400).

bearing a blood corpuscle of the Menobranchus, which displays, within what I deem to be its limiting membrane, a single crystal made up of all the cell-contents except the nucleus.[1] (Fig. 2.)

THE EXCRETORY FUNCTION OF THE LIVER.

BY

AUSTIN FLINT, Jr., M.D.,

PROFESSOR OF PHYSIOLOGY AND PHYSIOLOGICAL ANATOMY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

I HAVE selected as the subject which I shall have the honor to present to the Section on Biology, the Excretory Function of the Liver, for the reason that it seemed to me better to discuss a question concerning which I had made personal and original investigations, than to recite the observations of others, however interesting and important the latter might be. I have ventured to assume that the views which I have to offer are not without importance; and they are certainly not so familiar as many other topics which I might with propriety have selected. I shall, therefore, endeavor to bring to your notice, in the simplest manner possible, what I have myself learned with regard to the liver as an organ of excretion.

It is now well known that the liver has a variety of important functions with which physiologists are more or less completely acquainted. It produces a substance which is converted into sugar and is carried away in the torrent of the circulation. It secretes bile, which performs an important office in digestion. In addition to the digestive function of the bile, I think I have shown that this fluid serves as the vehicle for the elimination of at least one excrementitious principle, which is discharged in a modified form in the feces. If the liver serve as an organ of excretion, it is evidently of great importance, from a pathological as well as a physiological point of view, that we should have an accurate knowledge of the mechanism of this function. For a long time, many pathological conditions have been attributed to defective or perverted action of the liver; still, the terms, "liver complaint," "biliousness," etc., have failed to convey any definite pathological notion, and it is probably true that the liver has been accused of numerous sins of omission and commission without any positive scientific reason. Many medical writers have assumed, in an indefinite way, that the liver possesses an excretory function; but, so far as I know, no physiologist had ever described any definite excrementitious substance eliminated by this organ prior to my observations in 1862.

There are certain general laws applicable to secretions and to excretions, which it is important to consider in discussing the probable functions of the bile:—

I. Secretions have some useful purpose to serve in the economy, and, as a rule, they are not discharged from the body in health. Excretions have no function in the economy and are discharged from the body.

II. The flow of secretions from the glands is usually intermittent, occurring when their function is called into action. The flow of excretions is usually either constant or remittent.

III. The production of excretions depends upon the general process of disassimilation, which is constant. The production of secretions has no

relation to disassimilation, but is connected with processes which usually take place at intervals.

IV. The elements of secretion, which give to secreted fluids their characteristic physiological properties, are formed *de novo* in the glands themselves out of materials furnished by the blood, and they do not pre-exist ready-formed in the circulating fluid. The elements of excretion preexist in the blood, being taken up by the lymph or by the blood from the tissues, and they are separated from the blood by organs which have no part in their actual production; except that excrementitious substances may be changed one into another, as creatine into creatinine, or uric acid into urea.

V. When secreting organs are removed or destroyed, there is no vicarious production of the peculiar elements of the secretions; these elements do not accumulate in the blood; and the system suffers simply from the absence of the function of the special secretion. When excreting organs are removed or destroyed, there may be a vicarious elimination of the excrementitious principles by other organs, or the system may suffer toxic effects from the accumulation of excrementitious matters in the circulating fluid.

VI. The characteristic elements of true secretions are generally reabsorbed by the blood; but they are taken up in a modified form, so that they are not to be recognized in the circulating fluid. Elements of excretion are with difficulty reabsorbed by the blood after they have once been separated by the proper organs.

The applications of the foregoing general laws may be readily made to the pancreatic juice as contrasted with the urine, which two fluids we may take as types respectively of secretions and of excretions. Before we make an application of these laws to the bile, we may consider the simple question as to whether it can be shown that this fluid has a useful function to perform as a secretion. If the bile have no such function, an animal would live and maintain its normal condition if the bile were diverted from the intestine and discharged from the body. This question has been made the subject of experimental observation by simply cutting off the bile-duct, and making a fistula into the gall-bladder, by which the bile is discharged. The operative procedure involved is not difficult, but is very apt to be followed by fatal peritonitis, so that few experiments of this kind have succeeded. In the experiments which have succeeded, in the hands of Schwann, Bidder and Schmidt, Nasse, Bernard, and myself, the dogs have lived for thirty or forty days, dying with all the symptoms of inanition. In one remarkably successful experiment performed by myself, the dog lived for thirty-eight days, had a voracious appetite, and died at the end of that period after having lost about four-tenths of his weight. In this experiment, the bile-duct was ligatured in two places, and the intermediate portion was exsected. A fistula was then made into the fundus of the gall-bladder, which was kept open. The animal ate well the very day of the operation, and there was very little peritonitis. The only observation in which contrary results were obtained is one made by Blondlot.[1] In this case, a fistula was made into the gall-bladder after the bile-duct had been divided. The animal lived for five years, and, after fifteen days following the operation, was in good flesh and apparently suffered no inconvenience from the discharge of the bile

[1] Blondlot, Essai sur les fonctions du foie et de ses annexes, Paris, 1846, page 55, *et seq.*; and Inutilité de la bile dans la digestion, Paris, 1851.

from the fistula. During the first fifteen days the animal licked the bile from the fistula, but this was afterward prevented by a muzzle. After a time he made no attempt to lick the bile. Blondlot attributed the emaciation which occurred during the first fifteen days to this licking of the bile. When the animal died, more than five years after the operation, an examination of the parts was made in the presence of several physicians and students of medicine, and no communication could be found between the bile-duct and the intestine. From this observation, Blondlot concluded that the bile had no function in digestion, and that it was a purely excrementitious fluid; and he assumed that the cause of death in other experiments of a similar kind was the licking of the bile as it flowed from the fistula. In my own case of biliary fistula, in which the dog died after thirty-eight days, the animal was prevented by a muzzle from licking the bile.

The only point to consider, as it seems to me, in this single experiment of Blondlot, is whether or not a communication had been re-established between the bile-duct and the intestine. If such a communication existed, it would be easy to explain the survival of the animal. The following experiment, which I undertook for a different purpose, satisfied me upon this point:—

I attempted to estimate, in a dog, the entire quantity of bile discharged in the twenty-four hours. With this object in view, I cut down upon the bile-duct, emptied the gall-bladder, secured a canula in the duct, and attached a rubber-bag to the canula, for the purpose of collecting the bile. Twenty-three hours after the operation, the bag was in place and nearly full of bile. Just before the end of the twenty-four hours, however, the animal ruptured the bag, and the experiment, as far as its original object was concerned, was a failure. I then simply pulled the canula from the wound and set the animal at liberty. In about four weeks, after the wound had closed and the feces had become of normal color, the animal, being in a perfectly normal condition, was killed, and the parts were carefully examined in the presence of several assistants. It is well known that, in dogs, ducts that have been divided have a remarkable tendency to become re-established. In this case, inasmuch as no bile was discharged externally, and the feces were of normal color, it was certain that the bile was discharged into the intestine. Nevertheless, I searched for more than an hour for the communication before it was discovered. The only reasonable way, as it appears to me, to reconcile the single experiment of Blondlot with those of other observers, is to suppose that, in his observation, a communication between the bile-duct and the intestine had become established, which he failed to find. The difficulty which I experienced in finding the communication in my own observation led me to conclude that a communication existed in the case reported by Blondlot, which he did not discover.

It is in accordance with my own observations, as well as with those of other physiologists, to conclude that the bile is a secretion, and that it has a function to perform in connection with the digestive process, which function is essential to life.

Assuming that the bile has an important and an essential office in digestion, is it not possible that it may also serve the purpose of elimination, and contain elements of excretion? This is a view which has not been advanced by physiologists, who have regarded the bile either as a secretion or an excretion, and have not imagined that it could serve both functions. Before I take up the experimental facts bearing upon this

question, I propose to consider the arguments to be drawn from a study of the composition of the bile, and its discharge into the intestine. It was this idea which first led me to investigate the physiological relations of cholesterine.

The bile certainly has an important function as a secretion; and its flow, although not intermittent, is more abundant during the process of intestinal digestion. The peculiar biliary salts (the glycocholate and the taurocholate of soda) are formed in the liver and do not pre-exist in the blood. When the structure of the liver is invaded by disease so as to interfere with the production of bile, the biliary salts do not accumulate in the blood. The biliary salts are reabsorbed in a modified form in the intestine; for the quantity of one of their elements (sulphur) found in the feces is very much less than the amount discharged into the intestine.

On the other hand, with regard to one constant constituent of the bile (cholesterine), we do not know that it has any function in connection with digestion. The secretion of bile is continuous, although its flow is increased during digestion. Cholesterine, while it is an invariable constituent of the bile, exists in the blood and in certain of the tissues of the body.

The questions to determine experimentally with regard to cholesterine are the following:—

Is cholesterine produced in any of the tissues of the body?

Is cholesterine separated from the blood by the liver?

When the liver undergoes structural change in disease, does cholesterine accumulate in the blood?

Is cholesterine reabsorbed in the intestine or is it discharged, either unchanged or in a modified form, in the feces?

These are the questions which I endeavored to answer by a series of experimental investigations, made in the spring of 1862, and published in October of the same year, in the American Journal of the Medical Sciences.

Process for the Estimation of Cholesterine in the Blood.—The following is the process which I fixed upon, after a number of trials, for the quantitative analysis of the blood for cholesterine: The entire blood, serum and clot, is evaporated to dryness. The dry residue is then pulverized in an agate mortar, and treated for from twelve to twenty-four hours with ether, in the proportion of about one fluidounce of ether to one hundred grains of the original weight of blood. This is filtered, and the ethereal extract, which contains cholesterine and fats, is evaporated. The residue of this evaporation is then extracted with boiling alcohol, in the proportion of one fluidrachm for one hundred grains of the original weight of blood. This extract is filtered while hot, and the filtrate is evaporated, leaving the cholesterine and a certain quantity of saponifiable fats. To remove the saponifiable fats, add to the residue a weak solution of potash, and allow it to remain for about two hours; then dilute with water, filter, and wash the filter with water until the liquid which passes through becomes neutral. Dry the filter; wash it with ether; evaporate the ether; extract the residue with hot alcohol as before; evaporate the alcoholic extract, and the residue will consist of cholesterine, perfectly pure, as can be determined by means of the microscope. Using this process for the determination of cholesterine, a number

of observations were made upon dogs, from which I select the following as typical, the results having been repeatedly confirmed.

OBS. I. *Experiment showing an Increase in Cholesterine in the Blood passing through the Brain.* (The dog was not etherized.)

Blood from the carotid, 140.847 grains, contained 0.108 grain of cholesterine, or 0.768 part of cholesterine per 1000.

Blood from the internal jugular, 97.811 grains, contained 0.092 grain of cholesterine, or 0.947 part of cholesterine per 1000.

The increase in the proportion of cholesterine in the blood in passing through the brain was 23.309 per cent.

This observation, which was frequently repeated with the same general result, seems to show that the blood gains cholesterine in its passage through the brain. It is well known that cholesterine is always present in nervous substance—not in a crystalline form, but in a state of molecular union with nitrogenized and other matters. In order to verify this fact, I examined the brains of two subjects who had been killed instantly by accident while in perfect health, in one case finding a proportion of cholesterine of 7.729 parts per 1000, and, in the other, 11.456 parts per 1000.

The experiment just detailed was made with a view of determining whether or not the brain gives up cholesterine to the blood as it circulates through this organ; and the following experiment was made to determine whether the venous blood of other parts contains an excess of cholesterine. Theoretically, the blood of the femoral vein should contain a little more cholesterine than arterial blood, this excess being derived from the nerves of the extremity, although the increase would probably be not so great as in the blood of the internal jugular, which comes almost exclusively from the great nervous centre.

OBS. II. *Experiment showing an Excess of Cholesterine in the Blood of the Internal Jugular and Femoral Veins over the Arterial Blood.* (The dog was not etherized.)

Blood from the carotid, 143.625 grains, contained 0.679 grain of cholesterine, or 0.967 part of cholesterine per 1000.

Blood from the internal jugular, 29.956 grains, contained 0.046 grain of cholesterine, or 1.545 part per 1000.

Blood from the femoral vein, 45.035 grains, contained 0.046 grain of cholesterine, or 1.028 part per 1000.

The increase in the proportion of cholesterinc in the blood in passing through the brain was 59.772 per cent.

The increase in the proportion of cholesterine in the blood in passing through the lower extremity was 6.308 per cent.

This experiment confirms the previous observation upon the increase of cholesterine in the blood in passing through the brain, and it shows, in addition, that the blood gains cholesterine in other parts. Inasmuch as the nervous tissue is the only tissue in the extremities which contains cholesterine, it is probable that the excess contained in the blood of the femoral vein over the arterial blood was derived from the nerves.

It occurred to me that cases of old hemiplegia would present favorable conditions for verifying in the human subject the observations made on the lower animals. It has been ascertained that, when the function of nerves is permanently abolished, they soon become degenerated and their nutrition modified; and it seems probable that, if cholesterine be one

of their important products of disassimilation, the amount of cholesterine in the blood from paralyzed parts should be very small. Taking the blood, for example, from the paralyzed arm of a hemiplegic, this blood, coming from paralyzed parts, should contain less cholesterine than the blood from the sound arm. Of course, the blood from the arm contains no blood which has passed through the brain, which is assumed to be sound upon the paralyzed side. I examined, therefore, the blood from both arms in three cases of hemiplegia in the Charity Hospital on Blackwell's Island:—

CASE I. Sarah Rumsby, æt. 47, is affected with hemiplegia of the left side. Two years ago she was taken with apoplexy and was insensible for three days. When she recovered consciousness she found herself paralyzed on the left side. She says she had epilepsy four or five years before the attack of apoplexy. She has now complete paralysis of motion on the affected side, with the exception of some slight power over the fingers. Sensation is not affected. The speech is perfect and her general health is good.

CASE II. Anna Wilson, æt. 23, is affected with hemiplegia of the right side. Four months ago she became unconscious, and recovered in one day, with loss of motion and sensation on the right side. She is now improving and can use the right arm slightly. The leg is not so much improved because she will make no effort to use it.

CASE III. Honora Sullivan, æt. 40, is affected with hemiplegia of the right side. About six months ago she became unconscious, recovering the next day with paralysis. The leg was less affected than the arm from the first. Her condition is about stationary as regards the arm, but the leg has somewhat improved.

A small quantity of blood was drawn from either arm in these three cases. In each instance it was drawn from the paralyzed side with difficulty, and but a small quantity could be obtained.

The specimens were all examined for cholesterine, with the following results:—

OBS. III. *Quantities of Cholesterine in the Blood of the Paralyzed and the Sound Sides in three cases of Hemiplegia.*

CASES.	Blood.	Cholesterine.	Cholesterine per 1000 parts.
	Grains.	Grains.	
Case I. Paralyzed side . . .	55.458	....	The watch-glass contained 0.031 grain of substance, but the most careful examination with the microscope failed to show crystals of cholesterine.
Sound side	128.407	0.062	0.481.
Case II. Paralyzed side . .	18.381	....	Same as Case I.
Sound side	66.396	0.062	0.808.
Case III. Paralyzed side . .	21.842	....	Same as Case I.
Sound side . . .	52.261	0.031	0.579.

The conclusion from the experiments upon dogs and the three observations upon the human subject is inevitable, that cholesterine is produced in the substance of the brain and in the nervous tissue generally, as this substance is not contained in the muscular tissue or in any other parts except the crystalline lens, the liver, and the spleen. The question now to determine is the relation of cholesterine to the nervous system. Is it

one of the products of disassimilation of its tissue? If this be the fact, cholesterine is an excrementitious product, and it must be separated from the blood by some organ or organs and discharged from the body. Inasmuch as the bile always contains cholesterine, we naturally look to the liver as the organ for its elimination; for it is not found in the product of any other gland.

I employed essentially the same method in studying the question of the elimination of cholesterine as that used in determining the seat of its production, analyzing the blood going to and coming from the liver. Upon this point I made a number of observations, the general results of which were invariable. The following experiment is a type of these observations:—

OBS. IV. *Experiment showing that Cholesterine is separated from the Blood in its Passage through the Liver.* (The dog was etherized.)

Arterial blood, 159.537 grains, contained 0.200 grain of cholesterine, or 1.257 part of cholesterine per 1000.

Blood of portal vein, 168.257 grains, contained 0.170 grain of cholesterine, or 1.009 part of cholesterine per 1000.

Blood of hepatic vein, 79.848 grains, contained 0.077 grain of cholesterine, or 0.964 part of cholesterine per 1000.

The loss in the proportion of cholesterine in arterial blood in passing through the liver was 23.309 per cent.

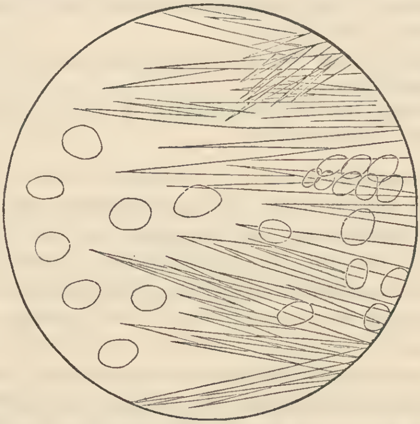
The loss in the proportion of cholesterine in the portal blood in passing through the liver was 4.460 per cent.

The bile always contains a certain proportion of cholesterine, which I found, in a specimen taken from the gall-bladder of a subject who had been killed instantly while in perfect health, to be 0.618 part per 1000. As I have demonstrated that the blood gains cholesterine in its passage through the brain and probably also from the general nervous tissue, that cholesterine is separated from the blood in its passage through the liver, and that cholesterine is invariably found in the bile and is discharged into the intestine, it seems to be proven that one of the functions of the liver is to eliminate this principle. If it can be shown that the cholesterine thus separated from the blood by the liver is discharged from the body, the fact that it is apparently produced in the nervous tissue and is taken up by the blood would point strongly to the conclusion that cholesterine is an excrementitious principle and is one of the products of disassimilation of the nervous matter.

Stercorine.—I made repeated examinations of the normal feces, with a view of determining the presence of cholesterine and its quantity. Although it is often stated by authors that cholesterine exists in the feces, I was unable to find it after the most careful examination, and I subsequently failed to discover any writer who had actually extracted it from the normal dejections. The process which I employed was essentially the same as that used in examinations of the blood, except that the extracts were decolorized by filtering through animal charcoal, and the alcoholic extract was treated with potash for one or two hours at nearly the boiling point. Treated in this way, the feces gave an extract which was non-saponifiable, but which did not crystallize for several days. It fused at a temperature of about 97° Fahr., while cholesterine fuses at 293°. After a few days, delicate, needle-shaped crystals began to appear, gradually increasing in number and breadth, and, as they became

broader, becoming split at the points and edges. These crystals presented all the characters of the crystals of a substance extracted from the serum of the blood by Boudet, in 1833 (Annales de Chimie et de Physique), which he called *séroline.* In some of my earlier observations upon the blood, I obtained these crystals; but I came to the conclusion that the so-called séroline was not a normal constituent of the blood, but was formed during the process used for the extraction of cholesterine. With this view, finding the so-called séroline a constant constituent of the normal feces, I called the substance stercorine, regarding it as one of the excrementitious principles of fecal matter. Crystals of stercorine are shown in the accompanying figure (Fig. 1). The rounded drops are probably composed of the same substance, as they disappear when the crystallization is complete. The idea that these crystals obtained from blood result from the transformation of cholesterine, is strengthened by the fact that the cholesterine of the bile is changed into stercorine in its passage through the alimentary canal. Stercorine, like cholesterine, is soluble in ether, very soluble in hot alcohol, and strikes a red color

Fig. 1.



Stercorine from normal human feces ($\frac{4}{10}$ inch objective).

with strong sulphuric acid. The points of distinction are the low fusing point and the form of the crystals.

I obtained from the feces of the twenty-four hours of a perfectly healthy man 10.417 grains of stercorine. It is estimated by Dalton that the total quantity of bile in twenty-four hours is 16,940.00 grains, and the total quantity of cholesterine, according to my estimate of 0.618 parts per 1000, is 10.469 grains, giving a difference between the estimated quantity of cholesterine and the actual quantity of stercorine extracted from the feces of only 0.052 of a grain. This sustains the idea of the change of the cholesterine of the bile into the stercorine of the feces.

Observations made by myself and others seem to show that the change of cholesterine into stercorine is incidental to the process of digestion. Cholesterine is found in quantity in the feces of hibernating animals and in the meconium, when, of course, there is no intestinal digestion, but when the bile is none the less discharged into the alimentary canal. I made an examination of human meconium and found cholesterine in the proportion of 6.245 parts per 1000, and no stercorine. I examined

the human feces in a case of simple jaundice from obstruction of the bile-duct, the feces being clay-colored, and found neither cholesterine nor stercorine. Nineteen days after, when the jaundice had disappeared and the color of the feces was normal, I found stercorine and no cholesterine. In the feces of a dog which had been deprived of food for forty-eight hours, I found stercorine and a small quantity of cholesterine. As far as can be learned from these facts and observations, then, it seems that the cholesterine of the bile is discharged in the feces unchanged when no digestion takes place, but that it is discharged in the form of stercorine under the ordinary and normal conditions of the digestive process.

Pathological Relations of Cholesterine; Cholesteræmia.—A knowledge of the relations of urea to nutrition bears so directly upon the pathology of renal diseases, that the pathological relations of any newly-discovered excrementitious principle assumes at once the greatest importance. If it be true that cholesterine, like urea, is a product of disassimilation, and that it is eliminated by the liver as urea is eliminated by the kidneys, we should expect to find, in cases of serious structural disease of the liver, an accumulation of cholesterine in the blood, or cholesteræmia, as we have uræmia in certain stages of extensive organic disease of the kidneys. It has long been observed, indeed, that, although simple jaundice due to resorption of the coloring matter of the bile is usually a trivial affection, there are cases of extensive change in the structure of the liver in which there is apparently a toxic condition dependent upon the presence of some excrementitious or poisonous substance in the blood. Pathologists have examined the blood in such cases with a view of ascertaining the nature of the supposed poisonous matter. Frerichs and others repeatedly examined the blood in cases of grave jaundice, expecting to discover the biliary salts or acids, but they never detected any substance which would react with Pettenkofer's test.[1] Becquerel and Rodier examined the blood in a case of jaundice and found "cholesterine excessively abundant," but they did not recognize the significance of this fact.[2] In such cases pathologists have looked for the biliary acids and their derivatives, and not for cholesterine. In order to throw some light upon the pathology of grave jaundice, Müller,[3] Kunde,[4] Lehmann,[5] and Moleschott[6] have extirpated the liver in frogs and kept the animals alive for several days, or even two or three weeks. On examining the blood, these physiologists failed to discover the biliary salts. They made no analyses of the blood for cholesterine. I hope to be able to show conclusively, by observations upon cases of disease of the liver in the human subject, that there may be an accumulation of cholesterine in the blood, or cholesteræmia, and that this occurs in certain cases of serious structural disease of the liver.

In cases of simple jaundice, there is resorption of the coloring matter of the bile from the excretory passages.

In cases of grave jaundice, which almost invariably terminate fatally, there is cholesteræmia, or accumulation of cholesterine in the blood.

1 Frerichs, Diseases of the Liver; New Sydenham Society, London, 1860, vol i. p. 95.

6 Moleschott, Comptes Rendus; Paris, 1855, tome xl. p. 1040.

There are cases of structural disease of the liver, in which there is no jaundice, but nevertheless there is cholesteræmia.

In the following cases, having first determined the proportion of cholesterine in normal blood, I examined the blood for cholesterine with reference to the points just stated:—

Obs. V. *Proportion of Cholesterine in Normal Blood.*

Male, æt. 35 . .	0.445	part of cholesterine	per	1000.
" " 22 . .	0.658	"	"	"
" " 24 . .	0.751	"	"	"

Obs. VI. *Case of Jaundice dependent probably upon Duodenitis.*—This case presented the symptoms of simple jaundice from temporary obstruction of the bile-duct. June 21, 1862, 212.428 grains of blood were taken from the arm. The proportion of cholesterine per 1000 was 0.508, which was within the limits of health, according to the results obtained in my examinations of normal blood. The feces, which were clay-colored, were examined, and I found neither cholesterine nor stercorine. July 11, the patient had entirely recovered; there was no jaundice; and the feces had become normal.

Obs. VII. *Case of Grave Jaundice with Cirrhosis.*—This case presented intense jaundice, ascites, great general prostration, and, toward the close of life, symptoms of blood-poisoning. The patient was admitted to the Charity Hospital on Blackwell's Island, June 16, 1862. On June 21, 50.776 grains of blood were taken from the arm. This blood contained a proportion of 1.850 part of cholesterine per 1000, an increase of 146.338 per cent. over the maximum quantity obtained from normal blood. The patient died June 27, 1862. There was double vision six days before death, and stupor for the last three or four days. The liver, examined after death, was in a condition of cirrhosis. The gall-bladder was contracted and contained but about two drachms of bile. The fibrous substance of the liver was increased in quantity, and the liver-cells were shrunken. The feces were taken a few days before death. The amount was small, only 272.1 grains in twenty-four hours, and contained 0.077 of a grain of stercorine. I found 10.417 grains of stercorine in the feces of the twenty-four hours in a healthy male.

Obs. VIII. *Case of Cirrhosis with Ascites and considerable affection of the General Health.*—In this case there was general prostration, confining the patient to the bed. After a tapping, the liver was explored and found to be considerably diminished in size. 117.193 grains of blood were taken from the arm, containing a proportion of 0.922 of a part of cholesterine per 1000, an increase of 22.769 per cent. over the maximum proportion obtained in my examinations of normal blood. In this case there were no nervous symptoms.

Obs. IX. *Case of Cirrhosis with Ascites and slight Constitutional Disturbance.*—This patient had suffered from ascites for eighteen months and had been tapped about thirty times. He is immediately relieved by tapping and goes out the next day. July 1, 1862, 251.567 grains of blood were taken from the arm, which gave a proportion of cholesterine of 0.246 of a part per 1000, or 44.719 per cent. less than the minimum obtained in my examinations of normal blood.

The cases just detailed, taken in connection with my observations upon animals, are certainly very striking. In the case of simple jaundice, which recovered, the proportion of cholesterine in the blood was within the limits of health. In the case of ascites, the patient not suffering much disturbance, the proportion of cholesterine in the blood was considerably below the normal standard. In the case of grave jaundice, which terminated fatally with symptoms of serious disturbance of the nervous system, the proportion of cholesterine in the blood was enor-

mously increased, being nearly three times greater than the maximum obtained in my examinations of normal blood. In the case of cirrhosis with considerable affection of the general health, the proportion of cholesterine in the blood was considerably above the maximum obtained in my examinations of normal blood.

Literature bearing upon the "New Excretory Function of the Liver," since the Publication of my Observations in 1862.

October, 1862.—My researches were published in the "American Journal of the Medical Sciences."

1868.—A translation of my memoir into French was published in Paris and presented to the Academy of Sciences for the Monthyon prize.

1869.—The commission from the French Academy of Sciences reported upon my observations and awarded an "honorable mention" with a "recompense" of fifteen hundred francs.

1869.—Grollemund (Thèse de Strasbourg) made observations upon the injection of the biliary salts into the blood in large quantity in dogs, and noted certain disturbances of the nervous system.

1869.—Tincelin (Thèse de Strasbourg) made observations in which he failed to obtain any marked nervous disturbances following the injection of the biliary salts into the blood in dogs.

1869.—Pagès (Thèse de Strasbourg) injected the bile-duct in dogs with a solution of sulphate of iron, which he thought destroyed the epithelium of the liver and interfered with its eliminative function, producing accumulation of cholesterine in the blood.

1870.—Feltz and Ritter (Journal de l'Anatomie, Paris, 1870) confirmed the results obtained by Pagès with the sulphate of iron. They found no marked effects following the injection of the biliary salts, taurine, or glycochol into the veins. They also injected cholesterine in soap and water. The cholesterine was not dissolved, and masses of cholesterine were found in the small pulmonary vessels, producing death by embolism.

1872.—Picot (Journal de l'Anatomie, Paris, 1872) noted an accumulation of cholesterine in the blood in a case of acute, yellow atrophy of the liver, which terminated fatally. He found a proportion of cholesterine in the blood in this case of 1.804 part per 1000, more than double the maximum which I obtained in examinations of normal blood.

1873.—Koloman Müller (Archiv für experimentelle Pathologie und Pharmakologie, Leipzig) made an elaborate series of experiments upon dogs. No serious or marked results followed the injection of the biliary salts or taurine into the blood. He rubbed cholesterine with glycerine and made a solution in soap and water. He injected 2.16 fluidounces of this solution, containing about 69 grains of cholesterine into the veins. In five experiments he produced "a complete picture of the symptoms of grave jaundice."

Conclusions of Koloman Müller.—"It appears to me to be certain that those cerebral symptoms which accompany severe jaundice and many diseases of the liver, the general manifestations of which have been called 'cholæmic intoxication,' are produced by an abnormal accumulation of cholesterine in the blood. This accumulation of cholesterine is contingent upon that alteration of the tissue of the liver, which, in such cases, it suffers more or less."

1875 and 1876.—Feltz and Ritter (Journal de l'Anatomie, Paris, 1875 and 1876) in opposition to their former experiments, conclude that the biliary salts injected into the blood produce grave changes, mainly in the blood corpuscles. The corpuscles become diffluent, change their form, the hæmaglobine transudes and crystallizes, and the power of absorption of oxygen progressively diminishes.

The general results of observations bearing upon the physiological relations of cholesterine, made since 1862, are confirmatory of my observa-

tions. As regards cholesteræmia, the experiments of Müller are the most important. Indeed, they supply the only missing link in my chain of experimental evidence; and they show conclusively that the symptoms of "grave jaundice," which I connected with cholesteræmia, may be produced by the artificial introduction of cholesterine into the circulation.

As an inevitable result of my observations, confirmed by others and extended by Koloman Müller, I can now confidently repeat the conclusions which I published in 1862.

Conclusions.—I. Cholesterine exists in the bile, the blood, the nervous matter, the crystalline lens, and the meconium, but does not exist in the feces in ordinary conditions. The quantity of cholesterine in the blood of the arm is from five to eight times more than the ordinary estimate.

II. Cholesterine is formed, in great part if not entirely, in the substance of the nervous matter, where it exists in great abundance, from which it is taken up by the blood, and constitutes one of the most important of the effete, or excrementitous products of the body. Its formation is constant, it always existing in the nervous matter and the circulating fluid.

III. Cholesterine is separated from the blood by the liver, appears as a constant element of the bile, and is discharged into the alimentary canal. The history of this substance, in the circulating fluid and in the bile, marks it as a product destined to be gotten rid of by the system, or an excretion. It pre-exists in the blood, subserves no useful purpose in the economy, is separated by the liver and not manufactured there, and, if this separation be interfered with, accumulates in the system, producing blood-poisoning.

IV. The bile has two separate and distinct functions dependent on the presence of two elements of an entirely different character. It has a function connected with nutrition. This is dependent on the presence of the glycocholate and taurocholate of soda, which do not pre-exist in the blood, subserve a useful purpose in the economy and are not discharged from it, are manufactured in the liver and peculiar to the bile, do not accumulate in the blood when the function of the liver is interfered with, and are, in short, products of secretion. But it has another function connected with depuration, which is dependent on the presence of cholesterine, which is an excretion. The flow of bile is remittent, being much increased during the digestive act, but produced during the intervals of digestion for the purpose of separating the cholesterine from the blood which is constantly receiving it.

V. The ordinary, normal feces do not contain cholesterine but contain stercorine (formerly called *séroline* from its being supposed to exist only in the serum of the blood), produced by a transformation of the cholesterine of the bile during the digestive act.

VI. The change of cholesterine into stercorine does not take place when digestion is arrested, or before this process commences; consequently, stercorine is not found in the meconium or in the feces of hibernating animals during their torpid condition. These matters contain cholesterine in large abundance, which also sometimes appears in the feces of animals after a prolonged fast. Stercorine is the form in which cholesterine is discharged from the body.

VII. The difference between the two forms of jaundice with which we are familiar, the one characterized only by yellowness of the skin and comparatively innocuous, while the other is attended with very grave symptoms and is almost invariably fatal, is dependent upon the obstruction

of the bile in the one case, and its suppression in the other. In the first instance, the bile is confined in the excretory passages and its coloring matter is absorbed, while, in the other, the cholesterine is retained in the blood and acts as a poison.

VIII. There is a condition of the blood dependent upon the accumulation of cholesterine, which I have called cholesteræmia. This occurs only when there is structural change in the liver, which incapacitates it from performing its excretory functions. It is characterized by symptoms of a grave character referable to the brain and dependent upon the poisonous effects of the retained cholesterine on this organ. It occurs with or without jaundice.

IX. Cholesteræmia does not occur in every instance of structural disease of the liver. Enough of the liver must be destroyed to prevent the due elimination of cholesterine. In cases in which the organ is but moderately affected, the sound portion is capable of performing the eliminative function of the whole.

X. In cases of simple jaundice, when the feces are decolorized and the bile is entirely shut off from the intestine, stercorine is not found in the evacuations; but in cases of jaundice with cholesteræmia, stercorine may be found, though always very much diminished in quantity, showing that there is an insufficiency in the separation of cholesterine from the blood, though its excretion is not entirely suspended. After death, but a small quantity of bile is found in the gall-bladder.

Discussion on Dr. Flint's Paper.

After the reading of the preceding paper, the President, Dr. John C. Dalton, of New York, said:—We have all listened with the greatest pleasure to the paper which has just been read. Though the subject is not entirely new, yet we are almost exclusively indebted to Dr. Flint for the latest light we have upon it. Those of us who are devoted to physiology are forced to select some particular department, and are therefore apt to be more interested in the development of that department than of others; but I am certain that if we make any distinction between the departments of physiology, physiological chemistry must be given the lead, for the study of the ingredients of animal forms lies at the foundation of all physiological study. We cannot claim that we are thoroughly familiar with physiology until we know the component substances of bodies—what they are, how they get into them, and what they do after getting there; what changes they undergo; and under what forms they disappear. The changes and operations of these substances constitute nutrition. Cholesterine, if I recollect aright, was discovered nearly a hundred years ago in gall-stones, was found to be extractible by hot alcohol, and was supposed to be an accidental deposit in an accidental, morbid form. But slow progress was made, and further discovery, until investigation proved that cholesterine existed in the liver. It was afterwards found in fresh bile, and then, after a considerable lapse of time, was shown to be an ingredient of the blood. Some years subsequently a curious discussion arose as to whether the nuclei of the red blood globules were not formed of cholesterine, and it was afterwards discovered that both the blood globules and the liquor sanguinis contained this substance, which was ultimately found in morbid exudations in all regions. Then came Dr. Flint's investigations in regard to the comparative amounts of cholesterine going to, and coming from, the organs. In this way the investigation has gone on for nearly a hundred years, and I suppose that Dr. Flint himself would not consider that the entire history of cholesterine has been yet exhausted. There is a great deal of work still to be done in this field to ascer-

tain the amount of cholesterine in the blood, and the different conditions and circumstances which determine its precipitation in morbid products. As we now know, it also forms an ingredient in some common articles of food. The study of cholesterine seems to me of the greatest importance in regard to excrementitious matters. I think we sometimes misrepresent to ourselves the character of the excrementitious process, in describing it as a process of destruction. But excrementation and disassimilation are not destruction; when food is taken into the stomach it undergoes a change there, and a further change in the blood, and so on, until it finally appears as carbonic acid or as cholesterine. Then comes the process of excrementation. The food has accomplished its duty in the nourishment of the body, and is wanted no longer. We could illustrate the process very well by all the steps upwards from the sowing of a cotton-seed to the manufacture of the cotton into cloth, and the final use of the rags in the manufacture of paper, and then the return of all the products back again to the soil. There are difficulties in the way of these investigations, and therefore we ought to feel ourselves very much indebted to those who help them on.

Dr. J. G. Richardson, of Philadelphia, said:—Dr. Flint's experiments establish three important facts in science, and complete a physiological chain in regard to the formation of cholesterine in the brain, its entering the circulation and being abstracted from the blood by the liver, and its being carried thence by the bile into the intestines where it is converted into stercorine. I would ask Dr. Flint whether he has made any experiments in regard to the formation of cholesterine in ovarian fluid?

Dr. Flint said:—I have not done so, but cholesterine is liable to be found in almost all the pathological formations of the body.

On motion, the conclusions of Dr. Flint's paper were adopted as expressing the opinion of the Section.

REPORT OF INVESTIGATIONS MADE UNDER THE DIRECTION OF PROFESSOR ZAVARIKINI, AT THE INSTITUTE OF NORMAL HISTOLOGY OF ST. PETERSBURG.

COMMUNICATED BY

PROFESSOR RUDNEW.

9

I. The Structure of the Sweat Glands in Man, in the Horse, and in the Sheep.

By Dr. Galani.

The epithelium of the sweat glands in man consists of very minute, oval cells, which are polygonal, and which are disposed in two layers, immediately under which lies the membrane consisting of fusiform elements with oval nuclei. By means of reagents we discover that these cells are simply muscular fibres. In the sweat glands of the scalp we find that these muscular fibre cells are intermixed with cells having the characters of connective tissue.

The epithelium of the sweat glands in the horse and sheep forms only one layer, while in all other animals there are two layers. The cells of this epithelium, viewed from the surface, have an hexagonal appearance, while from the side they appear of cylindrical form. Beneath the epithelium of the horse lie only the cells of connective tissue character, and these cells are so disposed one to another as to resemble in form a house tile. Beneath the epithelium of the sheep is found a membrane which consists of muscular fibres.

For the investigation of sweat glands we have employed the lens under which we have been able to separate the particles of the glands, and for the recognition of the muscular tissue we have used the following reagents, viz., a 36 per cent. solution of caustic potassa, chloride of palladium, carmine, and picric acid.

II. Upon the Termination of Nerves in the Pleura of the Rabbit, Dog, and Cat.

By Dr. Lebedeff.

The nerves, after separating into different arms and branches, terminate in a network in which it is sometimes possible to discover nervous cells of various sizes. Beneath the endothelium the network is composed of regular rhomboidal nooses, within which are found sometimes the cells of the endothelium, in numbers from one to five. Between the cells of the endothelium are disposed the fibres, which sometimes envelop the cell, and sometimes enter the cell and surround the nucleus. The greater part of the nerves possess nerve cells between their fibres, in number from two to fourteen, and this is especially observed in the rabbit. Some nerves do not terminate in the network, but in pear-shaped cells.

III. Upon the Microscopic Anatomy of the Nervous Apparatus of the Bronchi and Lungs in the Frog, the Rabbit, the Dog, the Cat, the Horse, and the Mouse.

By Dr. Santchich.

There are within the pleura many nerves which permeate the parenchyma of the lungs. The nerves form a double network, one being anterior and the other posterior. In each network are disposed from one to seventy cells, and the distributions are to the walls of the bronchi, the walls of the vessels, and the pulmonic pleuræ. The greater number of these cells are bipolar, and some few of them are even multipolar. All the nervous fibres emerging from the cells ramify to different parts of the lungs, and form networks. The nervous fibres found in the bronchi form two networks, one of these serving for two layers of the bronchi, and the other forming a surrounding network. The nervous fibres which go to the epithelium of the bronchi form a network exactly *under* the epithelium, and some of them at the same time penetrate the epithelium itself. If we isolate the epithelium cells, we observe that the nerve fibres are in intimate connection with the protoplasm of these cells. In the cartilage of the bronchi, viz., in the perichondrium, we find the minute fibres of the nerve, which sometimes penetrate into the upper part of the cartilage, but are more generally confined to the perichondrium. The glands of the bronchi are surrounded with a network of nerve fibres, which sometimes enter into the epithelium of the glands. In the bronchi and in the tissue of the lungs we meet with the terminations or ends of the nerve, in the form of either round or pear-shaped cells, and sometimes we find nerves which terminate in rhombic bodies, the nature of which is not at present known. The nervous fibres and networks are surrounded with the periaxial space, which space is covered with the epithelium cells. For examination the lung is stained with a solution of chloride of gold, one-half to twelve per cent., and sometimes with nitrate of silver and osmic acid.

IV. Upon the Termination of Nerves in the Human Skin.

By Dr. Santchich.

In the fibrous layer which lies immediately under the epithelium exists a nervous network of an extremely close and fine construction, the rhomboid meshes being very minute. This network does not contain nerve cells, except in very few cases, but within the fibrous meshes are to be found epithelium cells, in numbers from one to seven. The nerves, after permeating the Malpighian layer, terminate under the horny layer. If the epithelium cell with its nervous fibre be examined under the microscope in an isolated form, the fibre will be found in intimate connection with the protoplasm or body of the cell. Besides the network of nerves interlaced between the cells of the epithelium, there are seen minute fibres which do not take any part in the formation of the network, but which are also connected with the epithelium cells.

Within the outer sac of the root of a human hair is found a network of nervous fibres, some of which possess a pulp while some have none. Some of these fibres permeate the inner sac, and terminate in a minute network around the capillary vessels, while others pass through to the

epithelium, and here end between the epithelium cells. The papilla of the hair is supplied by the same network of nerves as the other parts of the hair follicle.

I may at this point describe the nerves appertaining to the fat glands and sweat glands of the skin. Around both, the nerves form a network. With the fat glands some of the nerve fibres lie either immediately beneath the epithelium or between the epithelium cells, and we have occasionally been able to distinguish how the nerve fibre, after passing into the fat gland, terminates in a body similar to a mulberry, with two or four nuclei. The networks of nerves which are disposed between the epithelium cells anastomose with each other, so that we can observe how the network of the papilla is combined with the nerves of the hair follicle.

We have worked under the microscope with chloride of gold solution, $\frac{1}{2}-\frac{1}{8}$ per cent., and for the isolation of epithelium cells we have used a 10 per cent. solution of common salt.

ON FUNGOUS GROWTHS IN SOLUTIONS FOR HYPODERMIC MEDICATION, AND THEIR PREVENTION BY SALICYLIC ACID.

BY

JOS. G. RICHARDSON, M.D.,

ATTENDING PHYSICIAN TO THE PRESBYTERIAN HOSPITAL, PHILADELPHIA.

Among the minor inconveniences of medical practice, few are more annoying to the careful physician than a failure to afford the hoped or prayed-for relief from pain, by the subcutaneous injection of morphia. I therefore venture to occupy a few minutes of the time of the Section with a brief account of a new method for preventing diminution in the strength of morphia solutions, in so far as it is due to the common cause of such deterioration, namely, the formation in the fluid of fungous growths, which necessarily develop at the expense of the contained solid ingredients.

If we examine under a microscope of high power one of the white flocculent masses which appear after a week or two of warm weather in our ordinary Magendie's solution of morphia, we will commonly find it made up of an immense number of branching threads, on an average about $\frac{1}{5000}$ of an inch in diameter, often distinctly septate, and probably recognizable as the mycelial condition of one of the genera of the Mucorini or siphonaceous plants.

Complete identification of the exact species is only possible, even for the professed mycologist, by investigation of its aerial fructification. We, however, often find, as it develops entirely beneath the fluid, an evident attempt towards the formation of some sort of reproductive body, and in many cases are to be seen in active motion, near the filaments, spore-like bodies, analogous to the antherozoids of the unmistakable algæ and fungi, which have doubtless escaped from broken fragments of the aquatic mycelial threads.

The atoxic quality of salicylic acid, as demonstrated by the moderate and even large doses administered in thousands of cases of acute rheumatism, etc., suggests at once its employment for the purpose of preventing the growth of these fungi; and I think it quite probable that it has already been so used by others of my fellow-practitioners as well as by myself. No exact observations upon this subject have, however, I believe, as yet been published, at least in our own country.

In order to determine the precise amount of this antiphytic agent required to produce the desired effect, I prepared on the first of August last, now five weeks since, one dozen two drachm vials, each containing one fluidrachm of a solution of acetate of morphia (gr. xvj to f℥j), such as is usually employed for hypodermic medication. These samples were numbered from 1 to 12, and after the acetate, except impurities, had been dissolved by the aid of a small quantity of acetic acid, I added to Nos. 2 and 4 each one-sixteenth of a grain of salicylic acid, to Nos. 6 and 8 each one-eighth of a grain of the same substance, and to Nos. 10 and 12 each one-

quarter of a grain of the like material. Nos. 1, 3, 5, 7, 9, and 11 were left unmixed with other ingredients, and all were corked tightly and equally exposed to the light, and to the unusually elevated temperature of our Centennial summer. At the end of one week, small whitish flocculi, evidently composed of filamentous tufts, were visible in the bottles the contents of which were unmixed with salicylic acid, and similar minute specks, in much less quantity, had made their appearance in Nos. 2 and 4, which contained each one-sixteenth of a grain of salicylic acid.

Under the microscope, specimens of these tufts were seen to be made up of mycelial threads, probably of some species of physomycetous fungi, such as I have already described. At the present time, after five weeks have elapsed, those vials which were not protected by salicylic acid present every one large masses of fungous growth, as each member of the Section may see for himself by inspecting them upon the table. Nos. 2 and 4, in each of which it will be remembered that one-sixteenth of a grain of the acid was dissolved, display small tufts of mycelial threads. No. 8 shows a mere trace of fungous growth, whilst Nos. 6, 10, and 12 exhibit to the naked eye (as they do also under a one-fifth objective) no indication of living fungi in the slight deposit of brownish impurities let fall at the bottom of the glass.

In specimens of similar morphia solution, containing one-eighth of a grain of salicylic acid to the fluidrachm, carried in the hypodermic syringe case, and used from time to time in my daily practice during three months of cooler spring weather, no flocculi of living fungi were discoverable with the naked eye or under the microscope. Further, no unusual effects of any kind were observable in patients, some of whom received as much as ♏viij at a dose. Injections made into my own arms for the purpose of testing the fluids in Nos. 10 and 12, produced but little smarting sensation, and afforded the ordinary anodyne, with no uncommon nauseating, depressing, or disagreeable effects of the drug.

I therefore recommend the preparation of a fluid for hypodermic injections according to the following formula: Morphiæ acet. vel sulph. gr. xvj; acid. acetici (No. 8), gtt. ij; acid. salicylic. gr. iss; aq. destillat. f℥j. If a sediment is left undissolved, this liquid should be filtered, or, after standing a few days in a vial, or preferably a conical glass, the clear fluid may be drawn off by means of the hypodermic syringe itself, and preserved for use. By employing such a preparation, the practitioner is almost certain to avoid the disappointment in the relief of pain liable to arise from injecting a solution, the strength of which has deteriorated, and he will also escape that danger of producing abscess by the insertion of fungous elements beneath the integument, against which we have been cautioned by some authorities, although perhaps without sufficient cause for the warning.

In conclusion, I would suggest that a similar application of salicylic acid to the preservation of watery preparations of quinia, atropia, etc., to solutions of bromide of potassium, citrate of potassium, etc., and to vegetable infusions, when it is desirable to avoid the employment of even small quantities of alcohol, may prove of great value to the pharmaceutist as well as to the physician.

Discussion on Dr. Richardson's Paper.

After the reading of the preceding paper, the President, Dr. John C. Dalton, of New York, said:—Dr. Richardson has referred to two disadvantages that might result in the hypodermic use of solutions of morphia without this precaution, but in language which leads us to suspect that perhaps he does not think much of the danger of producing an abscess. I would like to inquire whether there is any definite information in regard to the danger, or whether in his opinion the danger exists at all?

Dr. Richardson said:—Theoretically I have felt inclined to suppose that danger would exist, but in order to test the theory I have tried several experiments, injecting my own arm with a solution containing fungi, and in no case has an abscess been produced.

Dr. Dalton said:—Of course it would be more agreeable to inject a fluid not containing fungous growths; at the same time ought we to anticipate that these growths would continue their development in a subcutaneous tissue? My attention was once very directly called to the difficulty that might arise from such development. I made a series of observations in order to determine how many definite kinds of microscopic fungi might be derived from ordinary atmosphere. Taking fresh slices of boiled potato, I placed them on a plate that had been immersed in boiling water, and covered them with a bell-glass, under which also a moist sponge was placed. A considerable variety of these microscopic growths showed themselves from time to time, of various colors; and notwithstanding their minute size and apparent want of specific character, they had differences in form and size and structure. A few weeks after finishing the experiment, I found one day on the back of my hand a spot which was irritable and itching; this spread, two or three other spots appearing, until finally I was compelled to give attention to the matter, and on examination I found that my hand was the seat of a tricophyton, which was finally removed after treatment for four or five weeks. It then occurred to me that perhaps I had inoculated myself while engaged in the experiments. I had been raising microscopic fungi, and I had unknown to myself been infected with them. Further, upon the same subject, Dr. Vandoren told me that in a series of experiments he had demonstrated that the ovum of the mosquito is not deposited directly in the water, but floats in the atmosphere, and is brought down by the rain. So it would seem that in reality there are a larger number of germs, both vegetable and animal, that may arrive at their destinations through the elements. My impression is that this fact in regard to the ovum of the mosquito is new.

Dr. Richardson said:—My recollection is that our natural histories gave us pictures of the mosquito in the act of laying eggs in the form of a boat which floated upon the surface of the water for some days or weeks before hatching. I think the experiments mentioned are entirely novel.

Dr. Dalton said:—In regard to the boat in which the eggs are contained, is it barely possible that Dr. Richardson may be thinking of the mosquito itself coming out from the integument of the larva?

Dr. Richardson said:—No, sir; that is a subsequent performance. But I wish to ask Prof. Dalton in respect to the infection of which he spoke, whether his health had been deteriorated in any way? I make this inquiry because one of the most difficult questions in regard to the development of these entophytic and epiphytic diseases is whether the health is first deteriorated, so that a suitable *nidus* for the fungi to grow in is afforded, or whether, on the contrary, the fungi are the primarily active agents which deteriorate the health.

Dr. Dalton said:—I can testify, with the greatest confidence, that I was in perfect health.

Dr. Richardson said:—Some years ago I had an interesting case bearing upon this point in my own family. On the chin of my little daughter appeared

a small pimple, which became inflamed, and seemed to have a yellow head upon it. In examining it I was struck with its remarkably dry appearance, and its sulphur-yellow rather than brownish hue. I placed a portion of it under the microscope, recognized the presence of the fungus of Favus, and soon cured the disease with corrosive sublimate solution. The child was in perfect health, and I could only account for the attack by supposing that she had leaned her chin on the sill of a car-window, where some person infected with achorion Schonleinii had accidentally left a few spores of the disease. I would like to ask another question, whether there has been any corroboration or disproof of the experiments described by Simon in regard to the dependence of ocular diphtheria upon micrococci developing in the cornea of rabbits; where two punctures were made, in the one side with a diptherized needle, and in the other side with a clean needle, in every case the result having been that the cornea infected was marked with brownish streaks, which under the microscope displayed minute fungus spores. I look upon it as exceedingly important to know whether the fungi can develop in an internal portion of the system, secluded from the air, and that in a previously healthy part of the organism.

Dr. Dalton said:—I am not familiar with any corroboration of those experiments. I tried some experiments of a similar kind, two or three years ago, with results which convinced me that it did not require for such parasitic growths the previous existence of a morbid condition of the recipient. The experiments were with regard to the ordinary decomposition or rotting of fruit. It can no longer be maintained that rotting is a continuation of the ripening process. An external wound is absolutely necessary to the rotting of any fruit with a hard integnment, such as the apple and the pear, though it is not absolutely necessary with other fruit, like the orange. I tried the experiments with apples, and proved that they could be kept for any length of time, if uninjured, and also that rotting was contagious. The rot could plainly be seen to spread away from the point of contamination. I have exposed a dozen apples, half sound and half broken, to the ordinary atmosphere, and the rot always began at the point of injury. The spores came in from the atmosphere. Indeed, an injured apple can be kept from rotting by being protected from the atmosphere. I have taken a sound apple, and made a little cut in it, and then put it under a bell-glass, and kept it an indefinite time. The experiments can be easily tried, and are most convincing.

Dr. Richardson said:—You speak about the rot starting from the wound in the integnments of the apple in a way that resembled the spread of erysipelas from the edges of a wound in the human body. Did it ever occur to you to cover the wound in the apple with carbolized putty before exposing it to the infection of the fungi which cause decay, and thus throw a ray of light upon one of the great surgical problems of the day?

Dr. Dalton said:—I never did so, but I think that it might be an interesting experiment.

Dr. Richardson said:—I would ask Prof. Rudnew whether these experiments of Oertel and Nassiloff (the latter, I believe, a Russian observer), narrated in Prof. Simon's report, have been confirmed or disproved by others of his countrymen?

Prof. Rudnew, of St. Petersburg, said:—I have studied these investigations, but have made no similar researches myself, and believe that the views of those gentlemen are still considered *sub judice*.

THE MECHANISM OF JOINTS.

BY

HARRISON ALLEN, M.D.,

PROFESSOR OF COMPARATIVE ANATOMY AND ZOOLOGY IN THE UNIVERSITY OF PENNSYLVANIA, SURGEON TO THE PHILADELPHIA HOSPITAL, SURGEON TO ST. JOSEPH'S HOSPITAL, ETC.

The[1] limb being subservient to both support and motion, it is reasonable to expect that in certain joints the former function should be observed, and in others the latter. When the apparatus for support is conspicuous, the joint may be said to be of static value. But when this purpose is subordinate to flexion (*i. e.* deviation from the axial line of the limb), the joint may be said to be of dynamic value.

The most striking distinctions between the static and dynamic articulations lie in the relations of the opposed surfaces. To explain this portion of my remarks a few words of a general character are necessary. I premise that the typical "ball and socket" joints consist of well-defined balls embraced by perfect sockets. No such joints are found outside of the vertebral column. The articulations between the bodies of the vertebræ, although spoken of as amphiarthroses, are in truth "balls and sockets." The central intervertebral mass is the "ball;" the opposed vertebral surfaces and the peripheral interlacing fibrous bands of the disk make up the "socket." I also premise that the simplest forms, or at least the first forms, of joints appear in the vertebral column, since this structure answers to the axial line of the body. The movable union between any pair of segments or bodies of this axis may be taken as typical of what is possible under more complex conditions elsewhere. If it is remembered that a rod or axis cannot be projected far without segmenting, the best basis is secured upon which to rest any consideration of arthrosis. Obviously *motion* between a pair of bony segments is the main fact to consider in every problem. The questions which I believe can be asked with reference to further development of this theme are, in what way is *support* secured through a series of such mobile joints, and how can the apparatuses of *motion* be varied?

The limb is a special structure appended to the body. It moves chiefly at the joint between its first and second bones. This joint, in both the anterior and posterior extremities, is a ball and socket, as usually described. But it evidently in each instance is a portion of a ball opposed to a partial socket; since only small portions relatively of the head of the humerus or femur can be brought in relation to the socket at one time. So generally throughout the limbs (although in less marked degree), it is found that segments of spheroids play within concave surfaces. I propose to call all such surfaces modified balls and sockets (the type of which is exhibited only in the vertebral column), and proceed to define the two main varieties, named above, to wit: (1) Where the rela-

[1] [This paper is an abstract of a more elaborate study which the author reserves the right of publishing hereafter in a separate form.—EDITOR.]

tions between the two surfaces are such that the ball lies in its socket, and suggests *rest*. (2) Where the ball is suspended from the socket, and suggests *motion*. The occipito-atloid articulation is an example of the first, and the temporo-maxillary of the second variety.

The dynamic joints are apt to be crossed by powerful muscles, if indeed it may not be said of them that the muscles aid to a great degree in maintaining the efficacy of the articulations. Thus if the muscles about the shoulder-joint are divided, the humerus breaks contact with the scapula, and the joint is destroyed. This is also true of some other articulations, as the temporo-maxillary, in part. In some other instances of the same variety, the relation while not maintained by muscular action is strengthened by the presence of muscles crossing the joint, as at the ankle and wrist-joints.

As in all other studies in biological science, typical forms are united by intermediate ones. Some joints, as the knee and elbow, do not naturally fall within either static or dynamic kinds. The elbow-joint is especially difficult to study, it being varied from its type to a remarkable degree. The knee-joint, although exceedingly intricate, is resolvable in its several portions to static and dynamic functions, the structural modifications from typical points being pronounced. In the same way the first or swinging joints in the respective limbs, while of the same variety, since the ball is suspended from the socket in both, differ from each other in that the hip-joint is more fixed than the shoulder-joint. In a word the hip-joint is a dynamic joint, modified or specialized to do static work. In order that the work can be done effectively, stout bands cross its capsule, and the head of the femur is received within the acetabulum in such wise that the weight of the body is borne, not upon the centre of the head of the bone, but upon its upper surface.

If these general statements be remembered in studying the etiology of fracture and dislocation, more especially in examples of indirect violence, it will be recognized that a static joint will not be apt to be dislocated as long as the weight of the superincumbent mass presses directly within the socket. Thus a dislocation at the occipito-atloid articulation is rare, as is dislocation of the astragalus. But if the force be obliquely directed, causing the weight to be received violently against the side of the socket, then the joint may easily be luxated.

In the many positions assumed by the body, it often happens that an injury may be sustained from a reversal of the normal or typical relation. Thus while the extremities are described from the shoulder down, with the hands free (the main idea of the entire limb being *motion*), it becomes a different subject when studied with the limb suddenly assuming a *supporting* use—as for example when the body falls forward, and the hand strikes the ground while the limb is extended. Here the head of the humerus is driven up against its socket by the downward weight of the body, and the idea of swinging is lost. In a word, a dynamic joint is abruptly called upon to be a static one. A natural result is luxation of the shoulder, or, if the muscles about the joint be particularly rigid, fracture of the clavicle. In less degrees of violence, the force being expended nearer the hand, the wrist is either luxated or the radius broken. In medium degrees of violence, particularly seen in young subjects, the outer condyle of the humerus will break by the weight of the body being thrown through the convex radial head of the humerus downward upon the fixed concavity of the head of the radius, provided that the arm be forcibly extended. If the arm be partially flexed, the

weight of the body being transmitted to the forearm at an angle, the humerus will be apt to break transversely a little above the elbow-joint.

I do not speak here of the frequency of such fractures induced by indirect violence, but only of the way in which the articular surfaces as described would in my judgment behave under the circumstances detailed.

The lower limb, however, is always prepared for the conduction of lines of force so exceptional in the upper. The whole limb, while expressing motion, is also designed to sustain the weight of the body. Hence the greater strength of the joint surfaces, as well as the more prop-like appearance of the limb. In walking, the weight of the body is sustained for one moment at the astragalo-scaphoid joint in a nearly straight line, embracing, in the limb, the femur, tibia, and astragalus. The scaphoid bone and the inferior calcaneo-scaphoid ligament constitute a socket which receives and sustains this enormous weight. In falls from a height, which terminate by the foot striking, the weight not being received directly within the centre of the socket may be deflected, and luxation of the astragalus may occur. But from the rarity of this accident I infer that the mere exaggerations of the lines of force acting in its accustomed directions, are less injurious than the same kind of force acting upon the superior limb which is taken at a disadvantage.

The remainder of my remarks will be in application of the above data to the study of joints, including new observations of some special forms of articulation.

In the knee-joint, for example, I think that it can be shown, from the shapes of the articular surfaces, that the outer femoral condyle is the static or axial half, and the inner is the dynamic or swinging half. This study involves many details which would occupy too much time to elaborate.[1] Suffice it to say, however, that when a person stands erect, the femur rests upon the tibia as a ball in its socket, chiefly through its outer condyle. In flexion, this condyle is "switched off" (for the most part through the action of the popliteus muscle upon the outer semilunar cartilage), while the swinging of the inner condyle of the tibia upon the inner femoral condyle is initiated—not, it is true, by a ball suspended from its socket, as much as by a gliding of a shallow concave tibial surface upon a slightly convex femoral surface.

The term "switching off," as applied to the outer femoral condyle in passing from extension to flexion, needs explanation. The outer tibial condyle is observed to be convex toward the tibial spine. It is evident that, if any portion of the convex surface of the femoral condyle comes in contact with this convexity, no support is possible. This is what takes place when the knee is flexed. But when it is extended, the femoral condyle is placed firmly in a tibial concavity, the inner boundary of which is now formed by this eminence. As above stated, the outer semilunar cartilage is the factor producing the change. The outer tibial condyle is a true saddle surface, modified by the presence of the semilunar cartilage. The best example of a pure saddle surface is seen on the proximal surface of the trapezium. Here the convexity increases also toward the inner border. The first metacarpal bone of the thumb may be described as lodged upon this convexity in flexion of the thumb, and

[1] The details embrace the study of the cancelli of both femur and tibia, the shapes of the femoral, tibial, and patellar facets, the shapes and motions of the semilunar cartilages, as well as a refreshened account of the so-called crucial ligaments.

as relaxed or "switched off" in extension. It is evident that this lodgment and relaxation must be limited by appropriate ligaments. Inordinate or uncorrelated motions determine dislocation.

In the limbs of some lower animals, special adaptations in joints are recognized, which result in fixing or locking some of the facets. The immediate result of such locking is to conserve muscular power. Applications of this principle to some joints in the human frame may prove useful. Thus the knee-joint is nearly immobile at forced flexion or forced extension, but is freely movable at points between. It is probable that a careful study of other joint-surfaces will show similar peculiarities.

The facets upon the ends of bones are arranged in the order of the succession of the bones themselves in a given limb. The most evident arrangement is to have a facet upon the proximal and distal surfaces of each bone, in such wise as to allow the longitudinal axis to answer to the centre of each facet. These may be termed primary facets, since they are the most constant in any series of studies, and are least subject to change in special apparatuses. Assuming that the generalization of Goodsir is correct, that a process sent from the main shaft of a bone, as from the ribs of fishes and birds, may be termed a rayed process or actinopophysis, I will suggest that the same term may be given to the analogous process in a forked rib. If this be conceded, I think it not improbable that, in the event of the shaft of a bone and its actinopophysis becoming facet-bearing, such ray-borne articular surface should receive the name of actinic, or secondary surface. I believe that the inner femoral condyle is an instance of such a surface. I also believe that the surfaces upon the sides of certain bones, as those between tarsal and metatarsal bones, and between the tibia and fibula, or between the radius and ulna, are of subordinate value to the primary facets, since they appear to be caused by mutual compression of the bones themselves, and hence may be termed lateral or tertiary facets.

A joint may be said to be at rest when the least pressure exists between its opposed facets. The supine position will tend to rest static joints, since it diminishes the pressure of the weight. It will not, necessarily, so rest completely dynamic joints, since the muscles may be more or less active in the supine position. The lower jaw, for example, is not so rested. It is evident that to place in absolute rest a joint of this kind, its muscles must be kept from contracting. Any apparatus, therefore, to keep a joint at rest, must include all the muscles influencing the joint. When it is recalled that in the lower extremity the muscles are so disposed that the contraction of those arising from the hip effects changes in portions beyond the knee, and even down to the foot, it may be concluded that to make quiet any one, or part of one, of these surfaces, the entire limb should be kept quiet.[1]

It is at the same time true that, in a joint in which the articular surface on one side is larger than that on the other, those portions at any time not in use, may be said to be at rest. Thus, in the knee, some portions of the condyles are at rest in extension, while others are at rest in flexion. It follows from this that, in diseased action, products of pathogenesis will be absent from surfaces removed from pressure or friction.

[1] Rest is perhaps best secured at semi-flexion, *i. e.*, at the point at which extension ceases, and flexion has but just begun. All parts are then relaxed. This, while a theoretical point in some joints, has fixed value at the knee.

Now pressure long continued will destroy tissue, while friction will induce hypernutrition. It can be seen when a diseased joint is examined, with this fact in mind, at which points the pressure, and at which the friction has been. Thus in a knee-joint long the seat of chronic rheumatic arthritis, the outer condyle of the tibia will be found reduced in size, while the inner will be exaggerated. Also knee-joints flexed in diseased conditions will have points of pain localized at the inner side, while knee-joints extended in similar conditions will have like points developed upon the outer side.

If the outer condyle is axial, it will so remain, no matter what portion of the axis is reserved for articulation. So that in motion, after excision of the knee-joint, the line of axial support is preserved, and a good limb for *standing* is secured. But in consequence of the special apparatus for *flexion* having been removed, the limb below the knee is a mere wabbling appendage during attempts at bending.

Discussion on Dr. Allen's Paper.

After the reading of the preceding paper, the President, Dr. John C. Dalton, of New York, said:—The paper contains much that is new to me, while many things previously unexplained are now made clear. It has, however, occurred to me, as it undoubtedly has to the author, that he might have extended his principle also to the ligaments. I recall that while dissecting joints, as a student of medicine, after removing the external ligaments and retaining the capsule only, on bending the members making up the joint, it was impossible to say when certain parts were on the stretch and when not. It appears to me that this could also be explained by supposing the internal concave surface of the capsular ligament to be made up of a large number of facets operating in succession.

Dr. Allen said:—The occasion demanded that a single topic only should be discussed. Had time permitted, much could have been said upon the relation that articular surfaces bear to ligaments, both intrinsic and extrinsic. The fasciæ and muscles of every limb are also interested in every joint motion, and of the latter more particularly those that cross more than one joint. One series of these problems blends so easily into others that the line drawn between any two of them must necessarily be arbitrary. As Emerson has said, the answer to one riddle is another riddle. All our conclusions are relative, and invite renewed investigation. With reference to the ligaments of the knee-joint, it may be remarked that the great variety of function assigned to them by different writers is proof that their actions are not thoroughly understood.

Dr. Burt G. Wilder, of Ithaca, N. Y., having asked permission, as a visitor, to comment upon Dr. Allen's paper, said:—I understood Dr. Allen to say that the primary or fundamental movement of the limbs, among mammals, was forward and backward as with most quadrupeds, but that man had the power of raising the arms away from the trunk by means of the deltoid muscle, and that the head of the humerus presented a peculiar and characteristic facet, indicative of this movement of the limb. I would remind Dr. Allen of certain facts in embryology and comparative anatomy, well known to him of course, but apparently not present in his mind at the time of preparing his paper.

At a certain period of development, the forearm of man is in a state of pronation, as it is permanently in most quadrupeds, and afterwards acquires the power of complete supination, which seems to be correlated with the peculiar action of the entire limb alluded to by Dr. Allen. But, at a still earlier period, when the limbs have first appeared as little buds from the sides of the body, their narrow borders are forward and backward, while their flat surfaces

look outward and inward. Were any movement possible at this period, it is evident that to be effective it would have to be not forward and backward, but upward and downward, that is, *dorso-ventral*, and thus similar to that of which the human arm is capable in its greatest perfection in man's adult condition. In like manner, as far as we know, are developed the limbs of all Vertebrates; and the dorso-ventral or primitive motion is retained with most fishes and with the marine turtles. It is likewise persistent throughout life with the aquatic mammals, as the whales and porpoises, the manatee and dugong, the seal and beaver, and the curious duck-bill, or *Ornithorhynchus*, of Australia. It may be worth while to examine the shoulder-joint of these forms for the peculiar facet which distinguishes man from the ordinary quadrupeds.

At any rate, it seems somewhat significant that the dorso-ventral movement which, as Dr. Allen has stated, distinguishes the upper and nobler arm from the leg, and is likewise peculiar to man in his adult and perfect condition, in contrast with the monkeys and ordinary quadrupeds, should be also the primordial movement of both the arms and legs of all mammals, as indicated by the earliest condition of the limbs, and that it should likewise be retained in the case of certain low forms. In other words, the highest estate of man recalls his earliest condition, and suggests his relationship to the lowest members of his class.

Dr. Allen said:—While the act of walking expresses the swing of the anterior extremity, a yet better example of the characteristic motion of this part is swimming. This act, as performed by a man, is essentially different from the same act as essayed by a quadruped. In man, the arm is at one time forcibly abducted by a powerful deltoid. This muscle, in its distinctive shape, is not developed in the lower forms of animals, and in consequence the spinal play of facets between the scapula and humerus is, with them, absent.

SECTION ON SURGERY.

PRESIDENT OF THE SECTION.

JOSEPH LISTER, F.R.S.,

OF EDINBURGH.

VICE-PRESIDENTS.

J. A. GRANT, M.D., OF OTTAWA.

JOHN ASHHURST, Jr., M.D., OF PHILADELPHIA.

SECRETARY.

JOHN H. PACKARD, M.D.,

OF PHILADELPHIA.

On taking the chair, Professor LISTER said:—

GENTLEMEN:—

Although I am well aware that the time of this Section is exceedingly precious, I cannot refrain from expressing my deep sense of the honor I have received, an honor as great as it was entirely unexpected, in being called upon to preside over the Surgical Department of this great International Congress, sitting as it does in the chief centre of medical instruction on this vast continent. American surgeons are renowned throughout the world for their inventive genius, and boldness and skill in execution. It is to America that we owe anæsthesia, the greatest boon ever conferred upon suffering humanity by human means; from America came the ligature of the common iliac artery for aneurism; the ligature of the internal iliac for the same disease; the "extension treatment" by the weight and pulley for fractures of the thigh, and other injuries and diseases; the reduction of dislocation of the hip-joint by manipulation; and that model of ingenuity, which I cannot mention without alluding to the name of its inventor, Sayre's splint for morbus coxarius. These are but samples of what surgery owes to this country, and it might, therefore, well have been that some American surgeon should have been called upon to preside over this Section of the Congress. Yet I assure you, gentlemen, that highly as I esteem this honor, it is the more gratifying to me, because I am persuaded that it has not been conferred on account of any special merit of my own, but in consequence of the interest felt by the profession in Antiseptic Surgery, with which my name happens to be connected. It was the circumstance of my observing in the programme of the business of the Congress that the subject of Antiseptic Surgery was to come on first for discussion, that led me to cross the Atlantic; and I should be pleased, indeed, if the discussion which is about to take place should have the effect of strengthening the belief of the profession in the truth, the value, and the practical application of the principles of Antiseptic Surgery.

ANTISEPTIC SURGERY.

BY

JOHN T. HODGEN, M.D.,

PROFESSOR OF SURGICAL ANATOMY AND OF FRACTURES AND DISLOCATIONS IN THE ST. LOUIS MEDICAL COLLEGE, ST. LOUIS, MO.

Putrefaction is a decomposition experienced by animal substances when deprived of life and placed under special circumstances. The products of putrefaction are the results of the retrograde metamorphosis of nitrogenized substances. The process bears a striking resemblance to similar retrograde changes that occur in vegetable matters, resulting in the production of carbonic acid, alcohol, acetic and butyric acids, etc., while the products of the decomposition of animal substances are represented by carbonic acid, ammonia, butyric acid, leucine, sulphuretted hydrogen,[1] and many other matters whose chemical characters are not well established, and yet which cannot but be recognized as active agents in the production of septicæmia. Pasteur has shown that neither in vegetable nor in animal substances can putrefaction occur rapidly without the presence of living germs.[2]

Tyndall has, by the aid of electric light, and by almost innumerable experiments in reference to the development of living organisms, shown that the germs, without which putrefaction cannot be induced, and without which living organisms cannot be made to appear in vegetable and animal infusions, are found in unnumbered multitudes in the atmosphere.[3] The observations of Rindfleisch make it appear that these putrefactive and infusorial germs are abundant in water (terrestrial water), and less abundant,[4] and perhaps not even present, under ordinary circumstances, a few hundred feet above the earth's surface.[5] Tyndall has,

Treatment of Wounds by the Open Method and by Antiseptics. . . . . Atmospheric air carries the organisms which produce suppuration. . . . The air does not contain the organisms which produce decomposition, these are contained in terrestrial water and on all objects moistened by it.

[5] See The Antiseptic System, by A. E. Sansom, in which Schrœder and Dusch (in 1854 and 1859) testify that air passed through cotton-wool, which acted as a filter, was free from organisms. (p. 36.) "In 1860 M. Pasteur . . . filtering the air through a quantity of gun-cotton, dissolved the latter in ether, and thus obtained in a small space a number of bodies whose appearance announced them to be organized." (p. 35.) . . . He sowed the germs and produced organisms. "In some places the air was more fruitful than in others; especially its fertility diminished in proportion to the altitude from which it was obtained." (p. 36.) "In the air of sick rooms, hospitals, crowded halls, etc., many fungoid organisms have been noted by Trautman, Brittan, and Swayne, Dundas Thomson, Rainey, Lund, Lemaire, and

moreover, shown that, in the absence of currents of air, the germs do not reach infusions contained in vessels terminating in bent tubes, the ends of which are directed downwards, showing that germs must fall, or be carried by currents of air, into infusions, if they reach them at all, and establishing beyond a doubt that the specific gravity of the germs[1] is greater than that of the atmosphere.

Pasteur has determined that the ferments present different physical peculiarities,[2] so that the one may be distinguished from the other, and that they feed upon albuminoid substances.[3] Prof. Tyndall filled 100 tubes with infusions, and from the irregular manner in which the contents of the individual tubes were smitten, concludes that the germinal matter of bacterial life is not uniformly distributed in the air,[4] and thus accounts for the difference in the behavior of different wounds similarly circumstanced.[5]

The atmosphere of hospitals seems to be pervaded by living germs, and the walls and ceilings seem to be encrusted with them. Chalvet[6] found putrescible matters in the atmosphere and on the curtains, the windows, the walls and the ceilings of the Hospital Saint Louis. He also states that the vapor of water condensed near a suppurating wound is charged with irregular corpuscles resembling dried pus. "The experiments of Chauveau and Burdon Sanderson demonstrate that if a septic fluid capable of producing toxæmia when injected into the veins of a living animal be strained through a porcelain filter, the liquor so filtered may be injected with impunity, whereas the solid residue remaining on the filter retains in full force all the septic properties of the original fluid matter."[7] Mr. Lund found bacteria in the air of the Manchester Royal Infirmary.[8]

Septicæmia, in the surgical sense, expresses that condition of the blood which is induced by the presence of the products of putrefaction, a condition of the circulating fluid that unfits it for the proper performance of its function. Putrid matters may enter the circulation through any of the mucous, serous, or cutaneous surfaces, or from any part of the body in which they may be present.[9]

In surgery, the meaning is limited to the presence of putrid matters

Ransome. More recently Dr. Maddox has carefully examined the particles derived from the atmosphere," . . . and "found pollen grains, minute germs of fungi or protophytes, and excessively minute bodies, 'molecules,' 'globules,' etc." (p. 59.) "Dr. Percy found the dust of the British Museum to contain 50 per cent. of inorganic [Qu. organic?] matter. The latest investigations of this subject have been made by Mr. Tichborne, F.C.S. The following were the results of analyses: Street dust in Dublin contained organic matter 31 per cent. Dust from places of Public Concourse contained organic matter 32 to 53 per cent. Dust from Nelson's Pillar, 134 feet in height, contained organic matter 29 per cent." (p. 60.)

1 See The Antiseptic System, by A. E. Sansom, p. 58. Pasteur and Lister find that putrefactive germs are arrested in bent tubes.

2 See Sansom, p. 36. "By further researches Pasteur concluded that the different kinds of organisms met with in putrefying solutions differed widely in the conditions of their nutrition and their vitality. Some absorb oxygen and excrete carbonic acid; others the converse."

derived from the decomposition of the solids and liquids of the body itself; and these putrid matters may be formed either in parts in direct contact with the air, or in those with which the air does not come directly in contact.[1] Common observation indicates that absorption of these noxious matters takes place more rapidly in recent wounds, and in the early stages of inflammations, while the experiments of Billroth attest that after healthy granulation is fairly established, absorption of putrid matters goes on so slowly (if at all) that the phenomena of septicæmia are not presented. He says,[2] "Certain circumstances are necessary for putrid matters to be taken into the blood of man. Such substances are taken through the healthy skin and mucous membranes when the putrid substances have a destructive or cauterant action, or an active power of penetrating, like fungi and infusoria." "Diseased skin or wound-surfaces take up such putrid matters more readily, but even they only do so under certain circumstances; for instance, germs do not readily pass through well organized, uninjured granulations." "If we dress a nicely granulating wound on a dog with charpie dipped in the filthiest putrid matter, if the latter contains no cauterant substance that may destroy the granulating surface, the animal will not sicken; nothing will be absorbed. . . . If the septic poison be introduced into fresh tissue, it not only excites severe local inflammation, but quickly induces general fever."

Putrid pus is found in abscesses in many parts of the body; near the alimentary canal or respiratory passages, and in the soft tissues of the extremities, as well as in and about the bones, and, indeed, in every part of the body. A destructive inflammation may be set up about these collections, and the protecting walls may melt away and furnish more matter to undergo putrefaction, while the conditions left by their destruction will favor the absorption of septic matter. And it is probable that the septicæmia that so frequently follows the discharge of large collections of putrid pus is due, not so much to the admission of air and fresh agents active in the production of putrefaction, as to the rekindling of a destructive inflammation in the walls of such abscesses. This renewing of inflammatory changes may be due to the increased flow of blood to their walls, permitted by suddenly removing the pressure that may have, for an indefinite period, acted as a barrier to its entrance. The renewal of inflammatory processes from any cause in tissues surrounding collections of putrid matters is apt to be followed by septicæmia.

Certain conditions of the solids and liquids of the body are essential to the ready action of septic substances. In the physiological processes of the body, disintegrations and retrograde metamorphoses are constantly occurring as a consequence of vital actions, and the elements of the tissues assume a condition of fitness for putrefaction; all of the excretions are examples of these products. Febrile states, inanition, over-exercise, all induce changes in the organism that favor putrefaction in the solids and liquids of the body.

The impregnation of the tissues with certain substances tends to prevent putrefaction. Prof. Polli, of Milan, found that the bodies of animals that had been fed on the sulphites resisted putrefaction longer than those of similar animals not so fed, and that urine passed after taking sulphites remained "fresh, acid, and clear, and did not undergo ammoniacal fermentation for eight days during the hottest Italian summer." According

[1] Joseph Bell, M.D., Edinburgh Medical Journal, 1869, p. 982, *et seq.*
[2] Billroth, Surgical Pathology, American Edition, 1871, p. 334.

to Polli, these salts do not destroy the ferments, do not directly kill living germs, but modify the tissues so that they are incapable of being acted upon by catalytic germs, and thus putrefaction does not occur.[1] Prof. Gamgee's process of preserving meat consists in impregnating it with carbonic oxide and sulphurous acid.[2]

Any condition or any substance that opposes putrefaction is antiseptic, and, in its widest sense, this term includes many methods of action. In the surgical sense any agent which prevents those changes in the blood which ordinarily result from the rapid absorption of large quantities of putrid matters, must be regarded as antiseptic. Filters, used to prevent the contact of living germs with the putrescible discharges from wounds and the tissues, furnish a most admirable method of preventing septicæmia. A. Guérin, in 1870, used, at St. Martin's Hospital, cotton-wool as a dressing after amputations.[3] The great practical difficulty in the successful use of cotton lies in the fact that we cannot be sure that the cotton-wool itself does not contain germs which may become active in the production of putrefaction.[4] Attempts have been made to correct this possible condition by exposing the cotton-wool to air of an elevated temperature, and also by impregnating it with various substances, with the hope that germs already existing in the cotton may be destroyed. Prof. Lister, in 1871, prepared cotton-wool by diffusing through it chlorine gas, sulphurous acid gas, carbolic acid vapor, and vapor of benzine.[5] This end is attained by Prof. Lister in the use of his antiseptic gauze, with the advantage that it is a material which may be much more neatly and easily applied, and more readily rendered antiseptic, being in thin sheets, the fibres of which are all easily reached by the germ destroyer. Charcoal, animal and vegetable, is one of the best of protective dressings, acting (if a sufficiently thick layer be used) as a filter, and also as an absorbent by which the discharges are held until they may be removed; and, if putrefaction has actually taken place, the fetid emanations are held, and do not contaminate the surrounding air. Chalk, plaster of Paris, and clay, serve the same purpose as charcoal, but less efficiently. Powdered madder root[6] and Peruvian bark not only act as filters and condensers of fetid gases, but actually prevent putrefaction by destroying the activity of living germs, and, perhaps, by altering the escaping liquids so that they do not readily putrefy. Among the most valuable antiseptics are the metallic salts, as those of iron, copper, lead, zinc, mercury, and silver.[7] All of these used in a sufficiently concentrated state act as caustics, and less concentrated they simply condense the tissues, and alter the solids and liquids so that they do not readily putrefy; in addition to this action they destroy the vitality of the living organisms upon which rapid putrefaction depends, and also destroy noxious products.[8]

As a first application to a recent wound, perhaps, no substance of this

class is better than chloride of zinc, which coagulates at once the superficial layer of the albuminoid substances with which it comes in contact, and, coagulating the blood and lymph while yet within the mouths of the minute vessels, seems not only to prevent putrefaction, but also to render rapid absorption improbable.

Since the prevention of absorption is as efficient as the prevention of putrefaction[1] in avoiding septicæmia, this and a similar class of substances are among the very best antiseptics. Chlorine,[2] bromine,[3] iodine,[3] and the alkaline sulphites are active destroyers of germs and preservers of flesh, while the permanganates and manganates are chiefly valuable as scavengers,[2] as they hasten oxidation, and thus rapidly alter organic compounds to a degree that renders them incapable of putrefaction. Quinine,[3] salicylic acid,[4] salicine, benzoic acid, and boracic acid,[5] all destroy the vitality of bacteria,[6] and prevent and check putrefaction. Carbolic acid, creasote, and thymic acid, not only devitalize the germs, but alter the tissues so that they do not so readily undergo putrefactive changes, and alter recently wounded tissues so that absorption does not readily occur, but they do not destroy the products of decomposition.[7]

Drainage tubes[8] cannot be neglected in enumerating the valuable methods of getting rid of putrescible matters;[9] so, also, the water-bath, in which the water is continually changed, dilutes and carries away the putrid matters, and so prevents their absorption;[10] so, also, the contact of currents of dry air rapidly desiccating the putrid discharges, prevents both putrefaction and absorption. Alcohol and alcoholic tinctures[11] have attained considerable eminence as antiseptics, and no doubt owe their efficiency to the power possessed by alcohol of coagulating the albuminoid products of wounded surfaces, as well as of the tissues with which it comes in contact,[12] and also to the fact that in the manner in which they are employed, they seem by repeated changes to remove the putrescible matters before putrefaction can occur; they are, no doubt, farther beneficial in preventing absorption, since the change they effect in the tissues would render these less liable to the entrance of matters from without.

[12] Alcohol and Alcoholic Preparations in Surgery, etc.; by F. J. Batailhé and Ad. Guillet, Paris, 1860. See Amputations of the Thigh, by John Green, M.D., Boston Medical and Surgical Journal, June, 1863.

The value of the antiseptic treatment of surgical diseases is attested by many of the most eminent surgeons of Europe.[1] The practice is infinite in variety, extending from the simple protection of wounds from contact of catalytic germs, to the purification of hospital wards, water-closets, and grounds. So general is the practice of antiseptic surgery, and so thorough the faith of the profession in the value of its observance, that we find none so bold as to deny its value, or so reckless of the lives of his patients as to dare neglect its teachings.

One practises isolation as the surest method of preventing septicæmia, another has unlimited faith in ventilation and personal cleanliness;[2] one moves with deadly intent on the hosts of bacteria that infest his wards, another keeps watch over his wounds with a fidelity that challenges admiration; one places a barrier to the contact of the dreadful cause of putrefaction, another seals the absorbent surfaces and denies admission to the products of putrefaction; one leaves the wound open for the escape of the deadly enemy, another bars the paths of entrance so that none but the pure shall enter; one washes and scrubs, another plasters and daubs—all seek the same goal but by a variety of paths.

When we consider the fierce contest that for years has been waged in reference to the theory of the spontaneous generation of infusoria, and learn how difficult it is to prevent the entrance of germs into infusions; when we remember how difficult it is to prepare an infusion, and protect it, so that living matter shall not enter it from without, we cannot but realize the utter impossibility of protecting wounds from the contact of catalytic germs. Accepting as true the doctrine now so thoroughly established by Pasteur and others that fermentation and putrefaction do not occur except in the presence of living germs, and recognizing the presence of these germs in the blood of living human beings,[3] and their action as attested by the presence of collections of putrid matter in every part of the human body, we can readily see the utter hopelessness of a struggle to prevent by filters, plasters, or powders, their contact with open wounds.[4] Dr. E. Fischer found bacteria septica under Lister's dressings in every case, notwithstanding that all the cases, except one, had a favorable course.[5] Ranke and Von Birch-Hirschfeld found the same.

It should not be forgotten that through the various channels of excretion, septic matter may be eliminated from the body, and that if absorption is not more rapid than elimination, no poisoning occurs. If, therefore, we can keep the absorption of septic matters within bounds, we virtually prevent septicæmia. The practice of washing out the cavity of the uterus after the removal of fibroids affords a good illustration of the value of preventing a too abundant absorption of putrid matter,[6] as

does also the washing out of the uterus after giving vent to accumulations of old menstrual fluid (Emmett).

Some of the eminent German surgeons affirm that, during the Franco-Prussian war, a large percentage of the fatal results in gunshot wounds of the peritoneum was due to septicæmia, and that good results were obtained by repeatedly washing out the cavity.

Hervieux[1] urges the value of washing out the uterus in cases of puerperal metritis, and Fordyce Barker recommends the injection of carbolic acid solution four, five, or six times a day in the same disease. The washing out of the cavity of the chest after evacuation of pus, in empyema, the cleansing of putrid matters from abscesses and sinuses, all afford examples of the benefit of preventing the too rapid absorption of septic matter.

Good results are said to be obtained also by favoring the elimination of septic matters through the various emunctories of the body. Sulphite of magnesia has been used not only with the intent of protecting the tissues and destroying the septic germs, but also as an aid to the elimination of septic matters through the kidneys and intestines.

In connection with antiseptic surgery, the antiseptic ligature[2] cannot be ignored; most favorable results have been reported after its use. The advantages claimed are: (1) That it does not cause suppuration; (2) That it becomes absorbed;[3] and (3) That the ligature becomes organized,

II. On the different kinds of Ligatures employed in the treatment of deep-seated Cuts; by Eliaschewitsch, Russian Military Medical Journal, June, 1875; Centralb. f. Chir., 1875, No. 43.

I. The experiments, the conclusions of which we report here, have been made upon dogs and rabbits. Simple threads of catgut, soaked in chloral, and "catgut phenique" were employed in making the ligatures. All the ligatures on two or three dogs were soaked with juices; on the seventh day they were swollen, soft, and covered with a thin transparent layer of connective tissue; the knots were adherent to the surrounding tissue. The finest threads were re-sorbed in ten days, the catgut No. 4, of Lister, in from twenty to thirty days. This disappearance is effected by the division of the thread into fibrils which gradually disappear upon the contact of granulations. It requires the same time to be accomplished, whatever thread may be employed, provided that it is of the same dimensions. The simple thread of gut does not irritate in the least the neighboring parts; the thread soaked in chloral irritates them a little; the catgut a little more. As to consecutive hemorrhages after section of a large arterial vessel between two ligatures, Murinoff gives the following statistics: catgut, 10 per cent.; thread of gut soaked in chloral, 25 per cent.; simple thread of gut, 87 per cent.

II. Eliaschewitsch has sought to establish by experiments upon animals the different influence exercised by the threads of the suture according to their nature. Relating to inflammation, as to the influence which they exert upon the point of suture itself, he arranges them in the following decreasing order: Cotton, linen, silk (waxed silk being less irritating than raw silk), metal (whatever it may be), Florence thread, crin végétal, catgut phénique. The thread in a cord of non-carbolized gut irritates less than that covered with phenic acid, but it is less resistant. The presence of Florence thread or catgut in the depth of a wound does not hinder its reunion by first intention. The greater or less rapidity with which sutures cut, depends upon the irritation produced by the thread itself, and its degree of tension, and finally upon the condition of the lips of the wound. In the second series of experiments, Eliaschewitsch has endeavored to ascertain what becomes of catgut threads left in the wound. He has discovered that as soon as they come in contact with granulations they split up over their whole surface, and fibrils are detached which in their turn are divided into bits finally constituting only a granular detritus. The process began upon the fifth day in threads which had been used for ligatures of large arteries on a dog; at the end of a month no trace of a ligature was found.

and becomes a ring of living tissue surrounding and occluding the vessel.[1]

[1] Lancet, April 3, 1869. On Ligature of Arteries on the Antiseptic System; by Joseph Lister, Esq., F.R.S., Professor of Surgery in the University of Glasgow. . . . . In order to put the antiseptic animal ligature fairly to the test, I made the following experiment: Ligature of the carotid artery in the calf on the antiseptic system with threads composed of animal tissues.—On the 31st of Dec. 1868, I tied the right carotid about the middle of the neck in a healthy calf a few days old; the animal being under chloroform. Ligatures of two different kinds were employed at an interval of about an inch and a half, the sheath of the vessel being left undisturbed in the intervening part. The cardiac ligature was of home manufacture, composed of three strips of peritoneum from the small intestine of an ox, firmly twisted together into a threefold cord. The distal thread was of fine catgut, called "minikin-gut" by the London makers. Both had been soaked for four hours in a saturated watery solution of carbolic acid, which swelled and softened them so that the thread of my own making was too large to enter the eye of the aneurism needle, except near the ends, where it was thinner than elsewhere. This substantial ligature bore the strain of tying well, but the fine catgut broke as I tightened the noose; I did not, however, remove it, but, having a second piece at my disposal, passed it round at the same place, and with gentle traction completed the knot. There were thus two ligatures of the gut at the distal side. All were cut short except one end of the catgut, which I purposely left about three-quarters of an inch long to give a better opportunity of ascertaining what would become of the foreign material. . . . . A month (thirty days) after the operation, the animal, which had continued in perfect health, was killed, and the soft parts of the neck, below to the spine, were removed for examination. On dissection, I was struck with the entire absence of inflammatory thickening in the vicinity of the vessel, the cellular tissue being of perfectly normal softness and laxity. On exposing the artery itself, however, I was at first much disappointed to see the ligatures still there, to all appearance as large as ever. But had I borne in mind what I had observed in some of my earlier cases of compound fracture treated antiseptically, I should have been prepared to find these threads present in appearance, though absent in reality. It may be well for me to quote from the account I have before given of one of these cases. It was a compound fracture of the leg produced by direct violence, with a wound of considerable size, and a great deal of extravasation of blood into the limb. In accordance with the practice which I then followed, a piece of lint soaked with undiluted carbolic acid had been placed over the wound, and had formed with the blood a firm crust. Nearly three weeks after the accident, I was detaching a portion of the adherent crust from the surface of the vascular structure into which the extravasated blood beneath had been converted by the process of organization, when I exposed a little spherical cavity, about as big as a pea, containing brown serum, forming a sort of pocket in the living tissues which, when scraped with the edge of a knife, bled even at the very margin of the cavity. This appearance showed that the deeper portions of the crust itself had been converted into living tissue. For cavities formed during the process of aggregation, like those with clear liquid contents in a Gruyère cheese, occur in the grumous mass which results from the action of carbolic acid upon blood; and that which I had exposed had evidently been one of these, though its walls were now alive and vascular. Thus the dead but nutritious mass had served as a mould for the formation of new tissue, the growing elements of which had replaced the materials absorbed, so as to constitute a living solid of the same form. Hence it might have been anticipated that the ligatures of peritoneum and catgut placed on the calf's carotid would, after the expiration of a month, be found transformed into bands of living tissue. Such was, in truth, the case, as was apparent on closer examination. They had, indeed, a deceptive resemblance to their former condition from the persistence in their substance of the impurities of the original materials, the dark adventitious particles being of mineral nature incapable of absorption, so that they had remained as a sort of tatooing of the new structure. Nevertheless a marked alteration in color had taken place, especially in the distal ligature, where the dirty gray of the softened catgut had changed to a dirty pink tint.

The two pieces of catgut which had been tied round the vessel at that part had become, as it were, fused together into a single fleshy band, inseparably blended with the external coat of the artery. The knots were nowhere discoverable, and the only indication of the end which had been left long at the time of the operation was a black speck here and there upon a delicate thread of cellular tissue in connection with the vessel. The cardiac ligature was in like manner continuous in structure with the arterial wall. The short ends had disappeared; but the massive knot was represented by a soft, smooth lump, which appeared first entirely homogeneous, except that it was speckled with dark particles, as before referred to. On section, however, I discovered in the interior of the mass, and lying close

Prof. Lister says:—"Ample as was the evidence afforded to the naked eye of the organization of these ligatures, it was satisfactory to find it

to the wall of the artery, a small residual portion of the original knot, of comparatively firm consistence, and with the threefold twisted character of the cord plainly visible. It was quite distinct from the living tissues that surrounded it, so that it could be readily picked out from its bed with a pair of needles. A slender and irregular remnant of the noose was also found lying in a sort of tubular cavity, extending about half way round the vessel. Thus the process of organization had not yet quite invaded the entire thickness of the foreign solid, and it was a happy circumstance that the cord had been so constructed that the distinction between the old structure and the new could be plainly recognized. Ample as was the evidence afforded to the naked eye of the organization of these ligatures, it was satisfactory to find it confirmed in the clearest manner by the microscope. A bit of the knot having been teased out with the needles in a drop of water, presented, like a fresh piece of peritoneum, the wavy bundles of parallel fibres, characteristic of perfectly developed fibrous tissue. Adhering to the surface of the remnant of the ligature was some soft, opaque material, readily washed off with water, consisting of corpuscles of different forms, most of them caudate or fibroplastic, but some spherical, though not resembling pus; and here and there fragments of the original peritoneal tissue, affected more or less with interstitial cell development. At a short distance from the remains of the old thread, the fleshy material which had been formed at its expense proved to be a most beautiful example of fibroplastic structure, the coarse fibres which mainly constituted it being composed of very large elongated cells, often containing several nuclei, and presenting in their course branchings and thickenings of various forms. Here and there were some fibres more perfectly formed, and also cells of a more rudimentary character. Again, the band which had resulted from the organization of the two fine threads of catgut, which from the smallness of their bulk had no doubt vanished early, having had longer time to perfect its structure, was a comparatively well-developed form of fibrous tissue, consisting of coarse fibres rather than elongated cells, being thus intermediate between the merely fibroplastic condition of more recent growth and the completed texture of the original thread. For it is to be remarked that a piece of catgut exhibits, under the microscope, abundance of perfect fibrous tissue.

A more favorable period for the investigation, with a view to establishing the nature of the change which ligatures of animal tissue experience under antiseptic management, could hardly have been selected. Between the parts tied, the calibre of the artery was occupied by adherent coagulum, which was for the most part decolorized, and exhibited, under the microscope, fibroplastic cells of irregular forms. A similar clot was present between the distal ligature and a small branch that arose about a quarter of an inch beyond it. But between the proximal ligature and the heart the formation of a coagulum had been entirely prevented by a large vessel taking origin immediately above the part tied, which had thus borne for a month the full brunt of the cardiac impulses. Yet the vessel, so far from showing any sign of giving way, as it would inevitably have done had it been tied in such a situation without antiseptic precautions, appeared to have derived additional strength from the operation. The encircling ring of new tissue incorporated with the arterial wall must have had a corroborative effect, and within its grasp the inner coats which seemed to have been but imperfectly ruptured by the soft and substantial ligature were considerably thickened and had coalesced, so as to form a strong cul-de-sac, the irregularities of which had been smoothed over by a little fibrinous deposit, which had assumed the characters of a firm fibrous tissue, and presented a free surface, undistinguishable from that of the lining membrane of the artery. At the situation of the distal ligature, the structure of the vessel seemed entirely unaffected. The middle coat was seen in longitudinal section as a pink streak between two white lines, representing the external and internal tunics, neither thicker nor thinner than in the neighboring parts. The catgut threads had been tied too gently to produce rupture of the internal and middle layers, and their presence, and the constriction which they occasioned, whatever may have been their effect in the first instance, had left no permanent marks of the disturbance; while the fleshy band which had replaced them, though in time it would doubtless have dwindled to an insignificant filament, was at least a temporary addition to the strength of the artery. These appearances at the distal ligature are calculated to revive under a new aspect the old question whether it would not be better always to avoid rupture of the internal and middle coats, which could easily be done by using a pretty thick piece of catgut, softened by steeping it in a watery solution of carbolic acid. In this way the wall of the vessel would be left from first to last entirely intact. This, however, is probably a matter of indifference. Indeed, judging from the condition of the artery at the cardiac ligature, the injury done to the vessel at the outset by tight tying seems to lead to changes which increase its power of resistance, which was certainly severely tested in the present instance. It appears, then, that by applying a

confirmed in the clearest manner by the microscope;" and he adds, "It appears, then, that by applying a ligature of animal tissue antiseptically upon an artery, whether tightly or gently, we virtually surround it with a ring of living tissue and strengthen the vessel where we obstruct it."[1]
